Abstract

The development of sequencing technologies has led to monumental advances in the field of genomics, creating new areas of investigation and profoundly impacting our understanding of life itself. Presently, the “third generation” of these technologies is focused on improving the sequencing of long reads, which allows for studying complex areas in the genome. A promising platform offering long-read sequencing at a comparatively low cost is the Oxford Nanopore Technologies “MinION,” a USB-connected device the size of an ordinary dongle, which can be used in as good as any laboratory setting with a consumer-grade computer. Given that the technology is both recent and still under development, however, there is a need to formulate and verify adequate methodologies for a great variety of target species. In this thesis, a protocol for long-read sequencing of canine DNA using the MinION is presented. Four different HMW-gDNA extraction methods and five library preparation variants were evaluated in order to determine which approach would generate the best sequencing results. Additionally, a method for reusing flow cells in order to maximize data generated per cell and reducing costs was tested and deemed successful. Major challenges encountered throughout the project include DNA quality, fragment length, as well as high rates of pore loss and low pore occupancy. The best-performing DNA extraction protocol was an altered version of Qiagen's Genomic-tip 100/G. For library preparation, a modified version of Nanopore's Sequencing by Ligation kit (SQK-LSK109) had the most favourable results. The best sequencing run generated 14 Gbp of raw data in the span of 48 hours. The results presented herein constitute a first step towards the establishment of a method that leverages the MinION's advantages in canine genome sequencing projects.

Keywords: Oxford Nanopore, long-read sequencing, nanopore sequencing, canine genome.

Resumen

El desarrollo de tecnologías de secuenciación ha conducido a avances monumentales en el campo de la genómica, creando nuevas áreas de investigación e impactando profundamente nuestro entendimiento de la vida misma. Actualmente, la "tercera generación" de estas tecnologías se concentra en mejorar la secuenciación de lecturas largas, lo que permite estudiar áreas complejas del genoma. Una nueva y prometedora plataforma que ofrece secuenciación de lecturas largas a un costo comparativamente bajo es el "MinION", de la compañía Oxford Nanopore Technologies, cuyo tamaño, similar al de un adaptador USB, permite que pueda utilizarse en cualquier tipo de laboratorio. Sin embargo, dado que esta tecnología es relativamente reciente y aún se encuentra en desarrollo, es necesario formular nuevas metodologías que sean adecuadas para diferentes tipos de especies. Esta tesis presenta un protocolo para la secuenciación de lecturas largas de ADN canino utilizando el dispositivo MinION. Se evaluaron cuatro métodos de extracción de ADN de alto peso molecular y cinco métodos de preparación de bibliotecas con el fin de determinar qué protocolo produce los mejores resultados. Asimismo, con el fin de maximizar los datos generados por celda de flujo y reducir costos, se analizó un método para reutilizar celdas de flujo, el cual fue considerado exitoso. Los principales desafíos que se encontraron a lo largo de este proyecto incluyen la obtención de ADN de calidad y de alto peso molecular, así como la alta tasa de pérdida de nanoporos. El protocolo de extracción de ADN que produjo los mejores resultados fue una versión alterada del kit de Qiagen Genomic-tip 100/G. Para la preparación de la biblioteca, una versión modificada del kit de Secuenciación por Ligadura de Nanopore (SQK-LSK109) tuvo los resultados más favorables. El mejor experimento de secuenciación generó 14 Gbp en el lapso de 48 horas. Los resultados aquí presentados constituyen un primer paso para el establecimiento de un método que aprovecha las ventajas del MinION para proyectos de secuenciación del genoma canino.

Palabras claves: Oxford Nanopore, secuenciación de lecturas largas, secuenciación por nanoporos, genoma canino.

Acknowledgements

First, I would like to thank my advisors Tomas Bergström and Suvi Mäkeläinen for introducing me to this fascinating project and for always being there when needed. Without their invaluable support and guidance this thesis would not have come to fruition.

Next, I would like to express my gratitude to my examiner, Sofia Mikko, for her detailed review and valuable feedback, as well as to Christian Brandt, Ola Wallerman, and Oskar Karlsson, for always being willing to share their advice and ONT expertise.

I would also like to thank my laboratory partner, Nora Abdulkader, whose help and company made the long laboratory-hours pass by like a breeze.

Finally, I would like to thank my parents for their infinite support and encouragement, and my partner for being there for me every single step of the way, coffee and tea at the ready and acquiescing to many late-night proof-reading sessions. This accomplishment would not have been possible without them.

1 Introduction

1.1 The First Generations of Sequencing Technologies

Ever since its discovery, scientists have marvelled at the genetic code and its role in life. As sequencing technologies allowing its interpretation emerged, revolution in a great variety of fields, spanning from genomics and biotechnology to medicine and forensics, quickly followed.

The first generation of sequencing technologies was spearheaded by Sanger sequencing, also known as dideoxy chain termination method, which was developed by Sanger *et al* in 1977. This method relies on size-based separation of DNA fragments utilizing capillary electrophoresis, and the detection of dye-labelled dideoxy nucleotides (ddNTPs) at the end of each fragment. The order in which the fragments migrate through the capillary and the type of signal produced by their terminal ddNTP are used to infer the nucleotide order of the target sequence (*Figure 1*) (Maxam and Gilbert, 1977; Sanger, Nicklen and Coulson, 1977). For many years, Sanger remained the pinnacle of sequencing technologies; however, high cost and limited throughput impelled research and development of new methods, and soon a new generation of sequencing technologies emerged.

The next generation of sequencing technologies (NGS) is characterized by its high throughput and cost-efficiency, which is achieved by means of massive parallel sequencing of short reads. Roche's 454, launched in 2005, was the first product of this generation, but nowadays the Illumina platform dominates the market (Margulies *et al.*, 2005; Kchouk, Gibrat and Elloumi, 2017; Besser *et al.*, 2018).

The Illumina sequencing process starts by fragmenting the target DNA and attaching adapters to both ends of each fragment. The sample is then loaded into a flow cell covered by millions of complementary oligos that bind the DNA strands to the flow cell's surface. Thereafter, each fragment is multiplied by means of bridge amplification, which creates clusters of the same sequence. Then, a process called sequencing by synthesis (SBS) is performed; primers are attached to the DNA strands and a polymerase incorporates fluorescent-labelled nucleotides into the target fragment one at a time. Each base type produces a specific fluorescent signal that is detected and quantified by a camera, and then translated into a nucleotide sequence through a process called basecalling (*Figure 1*) (Bentley *et al.*, 2008; Illumina, 2019).

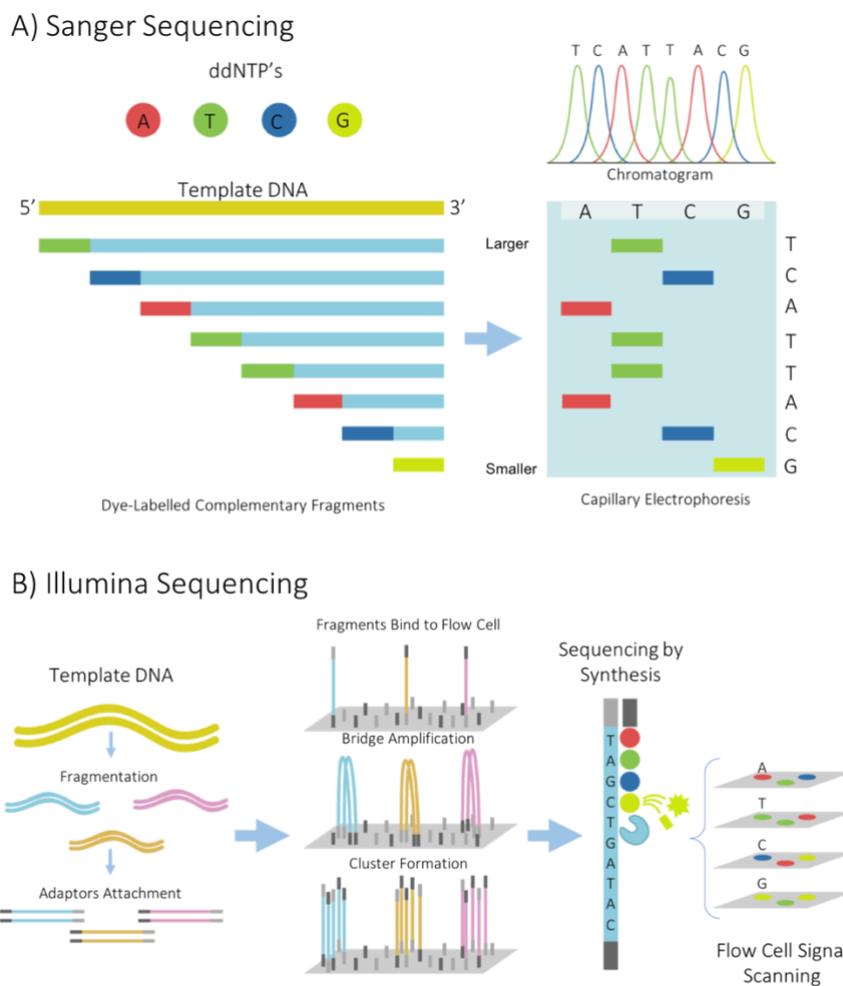

Figure 1. Examples of first and second generation sequencing technologies. A) Sanger sequencing process overview. B) Illumina sequencing process overview.

Compared to Sanger, NGS technologies have improved throughput by orders of magnitude at an accessible cost. The biggest drawback of these technologies, however, lie in their read length, which ranges from 50 to 500 bp, unlike Sanger sequencing that is able to achieve 1000 bp (Sanger, Nicklen and Coulson, 1977; Bentley *et al.*, 2008; Pollard *et al.*, 2018). Shorter reads can lead to fragmented genome assemblies, as well as limited resolution of repetitive regions and structural variations (Huddleston *et al.*, 2014; Ashton *et al.*, 2015; Bowden *et al.*, 2019). In order to overcome this limitation further developments were made, which soon gave rise to what is now commonly referred to as third-generation sequencing.

1.2 Third-Generation Sequencing

Third-generation sequencing, also known as long-read sequencing, is characterized by the use of amplification-free single molecule sequencing (SMS), real-time sequencing, and yielding output with vastly longer consecutive fragments (Schadt, Turner and Kasarskis, 2010; Heather and Chain, 2016; Pollard *et al.*, 2018).

1.2.1 Why Long-Read Sequencing?

Long reads offer several advantages over short reads; they can cover extensive areas in the genome, and thus highly complex regions with repetitive elements and structural variations such as insertions, deletions, inversions, and copy number variants, can be solved. They can also aid with phase resolution and the detection of paralogous regions, gene loss, fusion events, and so forth (Huddleston *et al.*, 2014; Ashton *et al.*, 2015; Goodwin, McPherson and McCombie, 2016; Fuselli *et al.*, 2018; Pollard *et al.*, 2018; Stephens *et al.*, 2018; Bowden *et al.*, 2019). With long reads, the accuracy of currently existing and *de novo* genome assemblies can be greatly improved, which in turn benefits our understanding of genomics, evolution, medicine, and many other scientific fields.

The Major Histocompatibility Complex (MHC) is a suitable example of a complex region that cannot be solved by short reads alone. This region is composed by a cluster of genes that participate in the regulation of immune responses and has been associated with a wide variety of diseases. Furthermore, this region is characterized by its high levels of polymorphisms and copy number variations (CNV), with the DRB exon 2 locus being one of the most polymorphic sites in vertebrates. This complexity makes the MHC an ideal target for long-read sequencing, as long reads are able to cover entire genes and intronic regions, close gaps, and solve CNVs and other structural variations (Beck *et al.*, 1999; Debenham *et al.*, 2005; Fuselli *et al.*, 2018).

1.2.2 Long-Read Sequencing Platforms: PacBio and Oxford Nanopore

The long-read sequencing market is currently dominated by two companies: Pacific Biosciences (PacBio, CA, USA), and Oxford Nanopore Technologies (ONT, Oxford, UK).

Pacific Biosciences

PacBio platforms (RS-II, Sequel, and the recently launched Sequel II) use what is called Single Molecule Real Time (SMRT) technology. PacBio's hardware consists of a chip, also referred to as SMRT cell, that contains well-shaped nanostructures called zero-mode waveguides (ZMWs). It is within these wells that sequencing is performed; a single DNA molecule with a pair of adaptors at each end is bound to a polymerase and fixed at the bottom of a well. Then, nucleotides labelled with fluorescent dyes are added, and every time they are incorporated into the strand by the polymerase, a fluorescent signal is released and detected (*Figure 2*) (Eid *et al.*, 2009; Rhoads and Au, 2015; Weirather *et al.*, 2017).

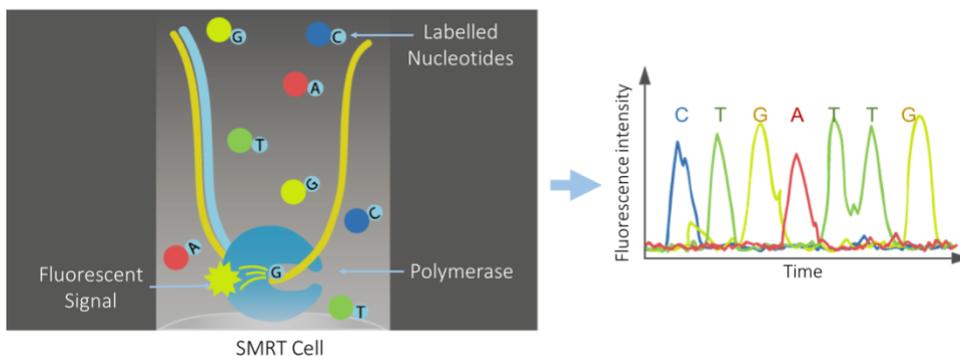

Figure 2. PacBio sequencing process overview. The polymerase incorporates labelled nucleotides into the template strand and a fluorescent signal is released and detected. The graph on the right shows a simplified version of how the sequence can be inferred from the fluorescent signal.

This innovative method is able to yield reads up to 100 kbp, with a raw error rate ranging from 11% to 15% (Korlach, 2015). To reduce this significant error rate, PacBio has designed a strategy called Circular Consensus Sequence (CCS), which requires the ligation of SMRTbell™ hairpin adaptors at both ends of the double stranded DNA (dsDNA), creating a circle-shaped molecule. The DNA passes through the polymerase multiple times and a consensus sequence is created (Eid *et al.*, 2009; Travers *et al.*, 2010; Korlach, 2015). For every turn the molecule completes, the error rate decreases. As an example, Eid *et al.*, (2009) report that 15

passes result in an average of >99% accuracy. Given that the number of sequencing passes is limited by the polymerase's lifetime, shorter fragments are able to complete more turns than longer fragments, and thus yield higher accuracy (*Figure 3*). Therefore, the trade-off between accuracy and read length must always be taken into account (Eid *et al.*, 2009; Travers *et al.*, 2010).

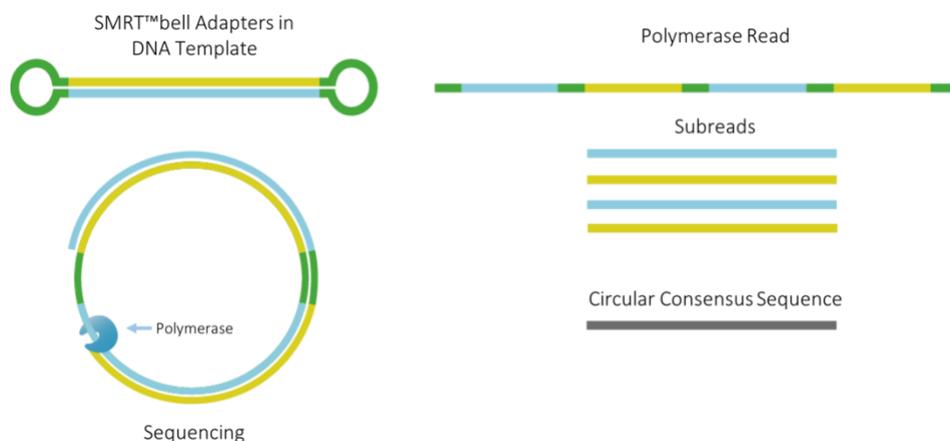

Figure 3. SMRTbell[™] approach for increased accuracy. Hairpin adaptors (green) are attached to both ends of the dsDNA fragment (blue and yellow) and create a circular molecule. The number of passes through the polymerase create a series of subreads that are used for creating a consensus sequence of high accuracy.

In addition to the high error rate, drawbacks of this technology include the high cost of its instruments and SMRT cells, as well as the stringent facility requirements (Weirather *et al.*, 2017). It should be noted, however, that a new PacBio platform called Sequel II was launched in April 2019. This new system claims to improve accuracy, yield larger quantities of data, and lower costs, but as of yet no user-based reviews have been published (PacBio, 2019).

Oxford Nanopore Technologies

Oxford Nanopore Technologies (ONT) focuses on the development of nanopore-based sequencing technologies. Their first product, the MinION, was introduced in 2014 and made commercially available in 2015. A characteristic feature of the MinION is its small size and portability; with dimensions not much larger than a regular USB dongle. Nowadays ONT offers four different sequencing platforms: the original MinION, the GridION, PromethION and the Flongle. All ONT devices use the same technology, differing only in their size and number of pores available (ONT, 2019a and 2019d).

The technology behind Oxford Nanopore sequencing is quite simple. Its hardware is comprised of a sequencing device and a flow cell that contains an electrically resistant membrane with 2048 nanopores, divided into 512 channels with 4 pores per channel, embedded on it. As for the sequencing process, specific adapters are ligated to both ends of a dsDNA fragment, after which motor enzymes are attached to the adapters, forming a DNA-enzyme complex. Once the sample is loaded into the flow cell, the complex is fixated to a nanopore and the dsDNA is unzipped, allowing for a single DNA strand to translocate the pore. Here an electric current is applied, and a sensor measures the changes in the ionic current caused by the different bases as the strand moves through the nanopore (*Figure 4*). The raw signal captured by the sensor is later translated into readable sequences by a basecalling algorithm (Kasianowicz *et al.*, 1996; Jain *et al.*, 2016).

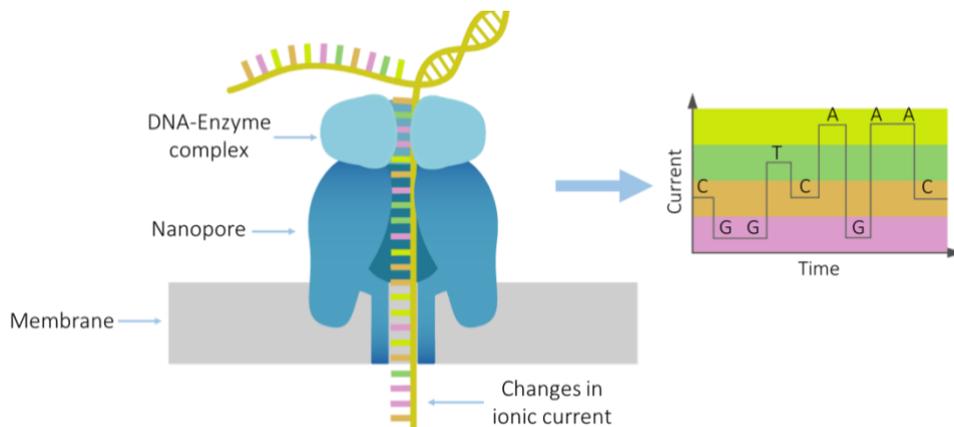

Figure 4. Oxford Nanopore technology overview. A strand of DNA passes through the pore while an electric current is applied. Changes in the current created by each base are recorded and translated into a sequence. The graph on the right shows a simplified version of how the sequence can be inferred from the different current signals.

Every nanopore run is controlled by the proprietary software MinKNOW™. This application provides a real-time visualization and analysis of the sequencing run, including metrics on pore and channel performance, output quantity, and read length distribution through a user-friendly interface (Figure 5). Additionally, MinKNOW™ offers the option to perform both sequencing and basecalling simultaneously, or to save the raw data as a .fast5 file for subsequent processing (ONT, 2019b).

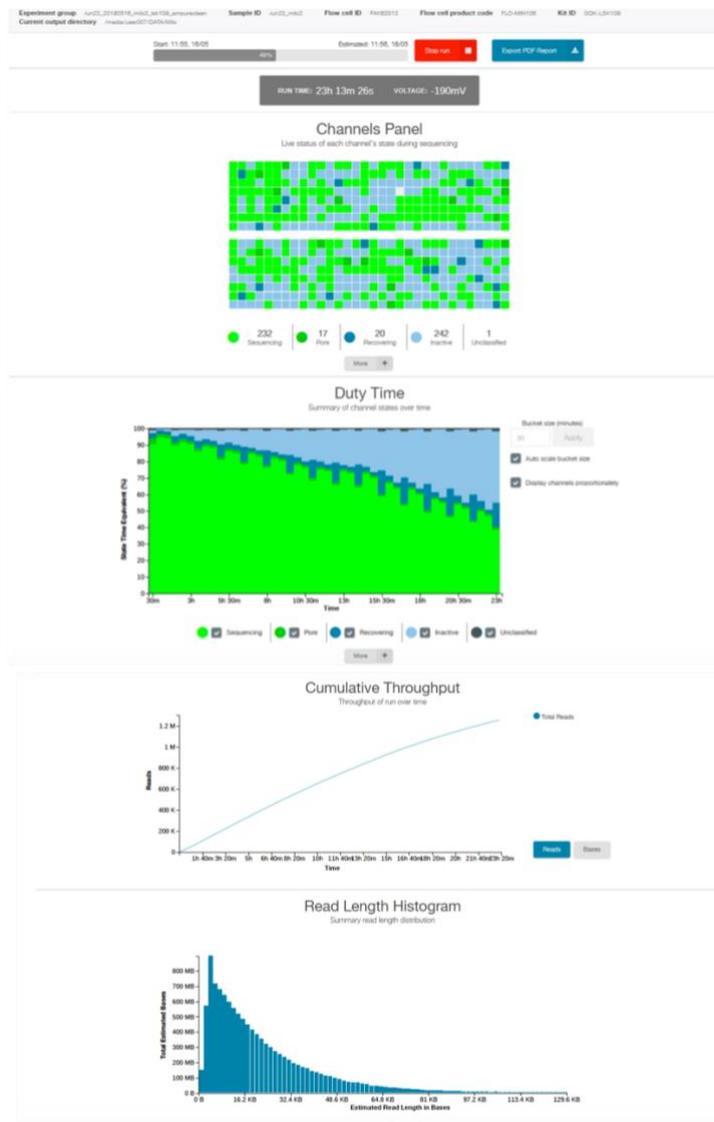

Figure 5. MinKNOW™ user interface. The channel panel shows the current state of the pores, while the duty time plot provides a summary of the state of the channels over time. The cumulative throughput reveals the amount of data collected during the run and the read length histogram shows the length distribution of the sequenced reads.

Because basecalling significantly affects the quality and accuracy of the resulting sequence, the selection of an appropriate basecalling tool is of utmost importance. Modern basecallers developed by ONT make use of Recurrent Neural Networks to improve the accuracy of base classification (Teng *et al.*, 2018). At the time of this study, ONT recommends using Guppy, a GPU-based basecalling toolkit with an integrated flip-flop model for homopolymer and read-accuracy improvement. This program takes the raw .fast5 files produced by MinKNOW™ and generates .fastq files in which the reads are encoded (Rang, Kloosterman and de Ridder, 2018; Teng *et al.*, 2018; ONT, 2019b). Fastq files can later be used for secondary data analysis such as read mapping, and *de novo* assembly (ONT, 2019b).

Oxford Nanopore sequencing is capable of generating two types of reads: 1D and 1D₂. The first type corresponds to the reads generated when a single strand of DNA is translocated through the nanopore. The second type, which is in an earlier stage of development, increases the probability of the ‘complementary strand’ being sequenced immediately after the ‘template strand’, creating 1D₂ consensus reads which can reach an average accuracy of 97%. In exchange for greater accuracy, however, the throughput is decreased (Brown, 2017; ONT, 2017).

The advantages of ONT’s solutions are numerous. First, the comparatively low cost and high portability of its MinION device makes it a viable option even in the smallest laboratory settings. As no fragmentation is necessary, the output read length is directly proportional to the input fragment size, with the current record of a successfully sequenced fragment being 2 Mbp (ONT, 2018). Furthermore, amplification by PCR is optional, and there is a wide variety of library preparation kits optimized for different purposes, including speed, throughput, and accuracy. Nevertheless, the error rate is still comparatively high, ranging from 5% to 15% depending on the read type, and the throughput per flow cell cannot match that achieved by Illumina (Goodwin, McPherson and McCombie, 2016; Jain *et al.*, 2016; Weirather *et al.*, 2017).

As a newcomer in the field, ONT is continuously improving their hardware and chemistry, as well as their supporting bioinformatics tools. In recent years, a wide variety of studies have relied on Oxford Nanopore as their primary sequencing device, achieving satisfactory results (Loman, Quick and Simpson, 2015; Jansen *et al.*, 2017; Fuselli *et al.*, 2018; Bowden *et al.*, 2019). Although these are all factors that inspire confidence in the ONT ecosystem and its suitability for future studies, it should be noted that a majority of these publications have been made on bacterial and viral models, therefore further research on other organisms is still required.

1.2.3 HMW-gDNA Extraction Methods for Long-Read Sequencing

Third-generation sequencing technologies are highly sensitive to the quality and length of the starting material. Therefore, isolation of high-quality and high molecular weight genomic DNA (HMW-gDNA) is of great importance (Mayjonade *et al.*, 2017; Michael, 2017; Gong *et al.*, 2019). Four of the most frequently used extraction methods are magnetic beads, anion-exchange resins, silica matrices, and phenol-chloroform.

Magnetic beads

The magnetic beads-based extraction protocol uses positively charged magnetic beads (usually a magnetic core coated with silica components) to which the negatively charged DNA is attracted. Once the DNA has been ‘wrapped’ around the magnetic beads, these are pelleted using a magnet, allowing for the unbound material (supernatant) to be removed with ease in the subsequent wash steps. The wash steps are performed in order to discard proteins, lipids, RNA, and other impurities. Finally, the DNA is recovered from the beads by using a low-salt concentration elution buffer (*Figure 6*).

The main advantage of this method is the reduction of the need for centrifugation, which can shear the DNA molecules and greatly reduce the fragment sizes of the final product (Levison *et al.*, 1998; Berensmeier, 2006). Furthermore, magnetic beads are efficient, easy to use, and can be implemented for additional DNA purification steps, where trace contaminants (e.g. detergents, enzymes, ethanol, salts, etc.) that could affect downstream applications are removed (Berensmeier, 2006).

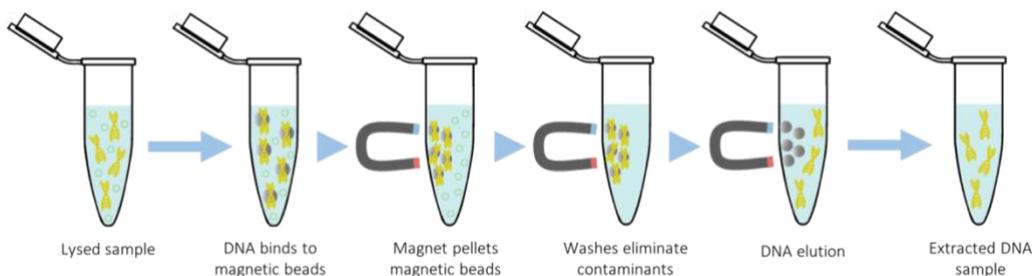

Figure 6. Magnetic beads DNA extraction process overview.

Anion-exchange resins

The anion-exchange resin is a popular extraction method that leverages the negative charge of the DNA molecule and its affinity towards positively charged diethylaminoethyl (DEAE) groups on the surface of silica beads-based resins. The DNA will remain bound to the resin as washes of low salt concentration buffers remove proteins, RNA, and other impurities. For the elution step, a high-salt concentration buffer is added and the DNA is recovered (*Figure 7*) (Budelier and Schorr, 1998). This extraction technique is implemented in some commercially available kits such as Qiagen's Genomic-tip, which uses large columns and gravity-based flow to prevent DNA fragmentation that could compromise the recovery of HMW-gDNA (Qiagen, Hilden, Germany).

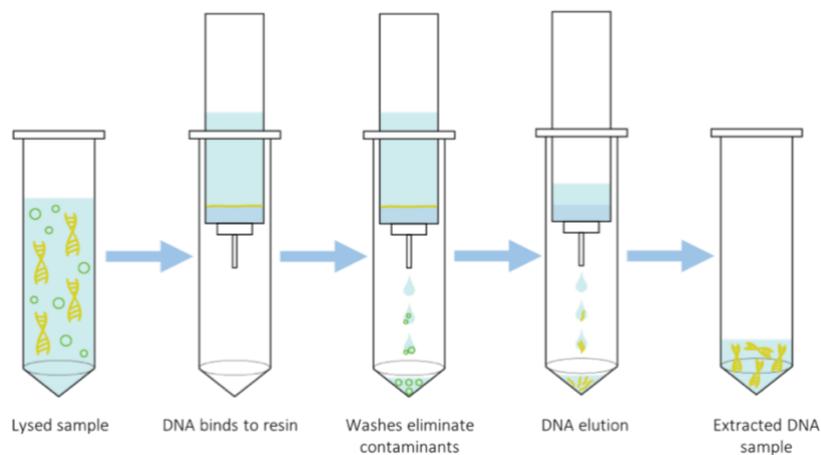

Figure 7. Anion-exchange resin DNA extraction process overview. This example is based on Qiagen's Genomic-tip extraction kit.

Silica matrices: spin columns

Nowadays, spin columns containing silica matrices have become one of the most common methods for DNA isolation. Similar to anion-exchange resins, spin column-based nucleic acid purification is a type of solid phase extraction that relies on the negative charge of the DNA molecule and its affinity towards the positively charged silica matrix. Once the DNA is bound to the matrix, several washes are performed to remove all impurities. Finally, the purified DNA is eluted by using a buffer with low ionic strength and a $\text{pH} \geq 7$, such as TE buffer or distilled water (*Figure 8*). When using spin columns, centrifugation is commonly used between sample loading, washing, and elution steps in order to pass the sample or buffers through the silica matrix. Albeit quick, easy to use, and capable of yielding high quality results, this method is not recommended for HMW extractions due to the

shearing that occurs due to the frequent centrifugation (Vandeventer *et al.*, 2012, 2013). Nevertheless, companies such as RevoluGen, have strived to develop spin columns that are able to generate HMW-gDNA that can be used on third-generation sequencing platforms (RevoluGen, Berkshire, UK).

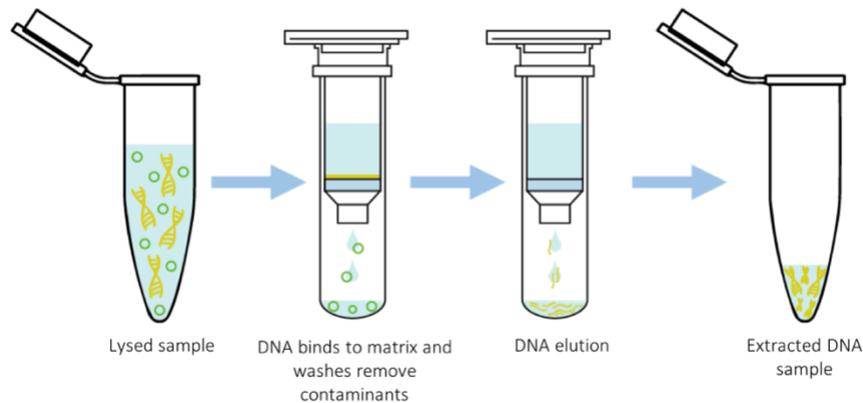

Figure 8. Spin column with silica matrix DNA extraction process overview.

Phenol-Chloroform

Phenol-Chloroform extraction is a well-known protocol capable of producing large quantities of high-quality HMW-gDNA, making it an attractive option for long-read sequencing purposes (Jain *et al.*, 2018). The drawback of this method is the extreme toxicity of both phenol and chloroform; utmost care must be taken when handling and disposing these reagents (Xu *et al.*, 2011, 2019).

This method uses organic solvents to separate proteins, lipids, carbohydrates, and other impurities from the aqueous phase, which contains mainly water and nucleic acids. Because of their different densities, the organic solvents containing the cellular debris will settle at the bottom (organic phase) whilst the aqueous phase will stay at the top (*Figure 9*). To isolate the DNA present in the aqueous phase, ethanol precipitation is carried out. Thereafter, the ethanol is removed from the DNA pellet, which is later dissolved using an elution buffer of choice. It should be noted that pH plays a key role in the isolation of nucleic acids, as DNA requires an alkaline environment to stay in the aqueous phase, while DNA-free RNA instead

remains aqueous in acidic conditions (Tan and Yiap, 2009; Sambrook, 2001; Xu *et al.*, 2011, 2019).

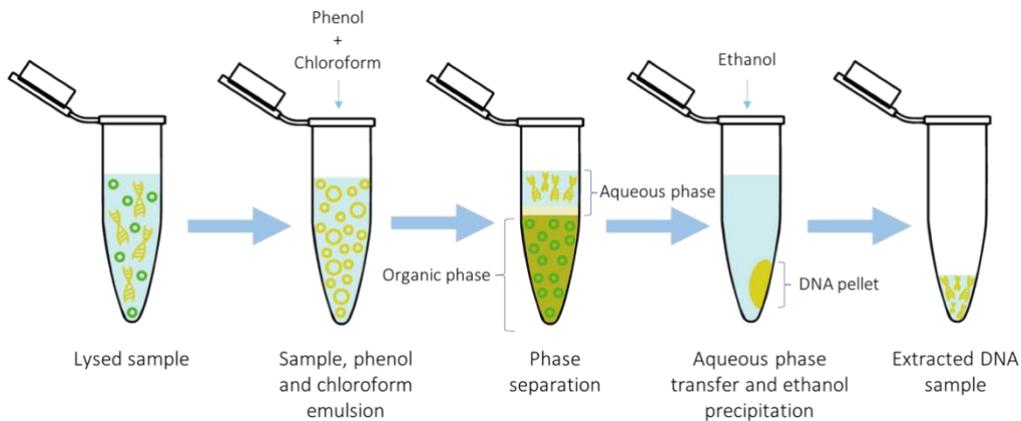

Figure 9. Phenol-Chloroform DNA extraction process overview.

1.3 The Dog as an Animal Model

The dog (*Canis familiaris*) is not just man's best friend, but an interesting species whose unique breeding history and phenotypic diversity make it an ideal animal model for research (Lindblad-Toh *et al.*, 2005; Mellersh and Ostrander, 2005).

The morphological variations and behaviour associated with each breed are powerful tools for detecting the genetics behind a series of traits that are complicated to trace in humans. Furthermore, dogs and humans share several diseases (e.g. diabetes, epilepsy, cancer, blindness, heart diseases, and hip dysplasia) and show similar symptoms, making the dog an exceptional animal for medical research (Lindblad-Toh *et al.*, 2005; Mellersh and Ostrander, 2005). Dogs are also useful for comparative analysis and evolution studies of the mammalian genome and other closely related species such as the wolf and other canids (Mellersh and Ostrander, 2005).

In 2005, Lindblad-Toh *et al.* (2005) reported the very first high-quality draft genome of the dog. This genome was built using a single individual (a boxer named Tasha) and sequenced using whole genome shotgun (WGS). This milestone in dog genetics permitted the development of a wide variety of studies, however dog breeds are quite different from each other, and using a reference genome of a single breed has its limitations.

Holden *et al.* (2018) estimate that 27% of the total genetic variability in the dog genome corresponds to variations between dog breeds, whereas human genetic

differentiation ranges between 5 and 10%. This suggests that the current canine reference genome, although a valuable baseline, might not be entirely representative of every single breed.

Breed-specific sequencing could potentially be used for screening genetic variations that are unique or shared among several breeds, offer more information about the evolutive background of the breed or group of breeds of interest, improve the reference genome, and aid in the detection of genetic diseases (Holden *et al.*, 2018).

1.4 Aim

The aim of this thesis was to develop a method for performing long-read sequencing of canine DNA using Oxford Nanopore's MinION device. This method would be used in a parent project which investigates the evolutionary trajectory of Nordic dog breeds and how they might vary from other breeds.

2 Methods

2.1 Animal Samples

Blood samples from seven dogs of different breeds were collected, in EDTA vacutainers, and stored at 4 °C. Every sample was divided into several aliquots, with the volume for each aliquot depending on the total volume of blood that was obtained during the sampling, allowing for various DNA extractions to be performed per individual (*Figure 10 and Table 1*).

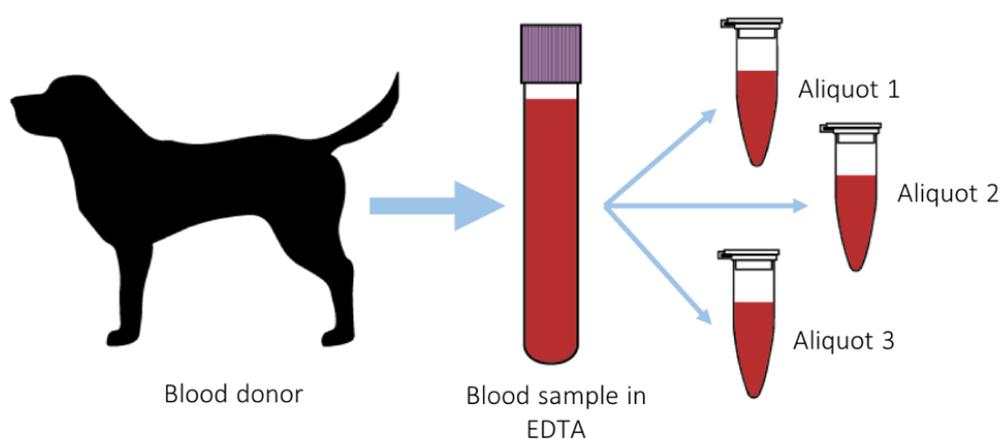

Figure 10. Blood sample processing workflow. Each blood sample was divided into several aliquots so several extraction and sequencing tests could be made from the same individual.

All samples were processed within a 24-hour timeframe to ensure that only fresh blood was being used during extraction, with the exception of sample SVH1_2 which was processed 15 days after extraction (*Table 3*).

Table 1. Sample list. Column 1. The dog ID is composed of a three-letter code that refers to the individual's breed, followed by a unique number. Column 2. Each blood sample was divided into several aliquots which were identified with an aliquot ID number. Column 3. The blood volume corresponds to the amount of blood taken per aliquot. Column 4. The column contains the breed of each individual.

2.2 HMW-DNA Extraction

Four HMW-DNA extraction protocols were tested in order to evaluate their suitability for nanopore sequencing. In *Table 2*, a brief summary of the protocols, and their expected outcome based on the documentation provided by each kit, is presented. A complete list of the reagents used in this project has been included in Appendix 1.

Table 2. Summary of tested HMW-DNA extraction protocols. All specifications were obtained from the corresponding manufacturers.

Extraction method	Company	Principle	Whole-blood input	Total yield	Fragment length
MagAttract® HMW DNA Kit	Qiagen	Magnetic beads	200 µl	4-8 µg	100-200 kb
QIAGEN Genomic-tip 100/G	Qiagen	Anion-exchange column	1-5 ml	80-100 µg	50-100 kb
Fire Monkey	RevoluGen	Column based	1 ml	8 µg	100-130 kb
Phenol-Chloroform	-	Organic solvent	*	**	**

*Sample volume can vary. **Metric varies according to sample quality and volume.

2.2.1 MagAttract® HMW DNA Kit

The MagAttract® HMW DNA Kit is a magnetic bead-based protocol manufactured by Qiagen (Qiagen, Hilden, Germany). Samples GRE1_1 and SVH1_1 were extracted using this kit following the manufacturer's instructions that are described below.

For this protocol, 20 µl of proteinase K were pipetted into an empty 2 ml Eppendorf tube, followed by 200 µl of fresh whole-blood, 4 µl of RNase A (100 mg/ml), and 150 µl of Buffer AL. This was mixed very carefully by tilting and tapping the tube. After 30 minutes of incubation at room temperature (RT), 15 µl of MagAttract Suspension G (magnetic beads) and 280 µl of Buffer MB were added. The magnetic beads were resuspended by gently tapping the tube and then spun down by microcentrifugation. Next, the tube was incubated in a thermomixer at RT for 3 min at 1,400 rpm and then placed into a magnetic rack for ~1 min or until the magnetic beads were completely pelleted. The supernatant was removed, and the tube detached from the magnetic rack. Then, a first wash step was performed: 700 µl of Buffer MW1 were added, followed by an incubation at RT for 1 min at 1,400 rpm. After this, the beads were pelleted again by placing the tube into the magnetic rack and the supernatant was removed. A second wash was carried out following the same steps as the first one. With the tube still attached to the magnetic rack and without disturbing the pellet, 700 µl of distilled water were added, incubated for 1 min at RT, and then removed. This step was repeated twice. Finally, the tube was removed from the magnetic rack and 100 µl of Buffer AE (10 mM Tris-Cl; 0.5 mM EDTA, pH 9.0) were added followed by an incubation at RT for 3 min at 1,400 rpm. Once again, the beads were pelleted in the magnetic rack and the supernatant, which contains the final product, was pipetted out and transferred into a clean 1.5 ml Eppendorf tube.

2.2.2 QIAGEN Genomic-tip 100/G

The QIAGEN Genomic-tip 100/G, in combination with Qiagen's Genomic DNA Buffer Set, is an anion-exchange, gravity-flow, column-based protocol that allows the isolation of high yields of HMW DNA (Qiagen, Hilden, Germany).

QIAGEN Genomic-tip 100/G: Leukocyte nuclei extraction

The QIAGEN Genomic-tip 100/G protocol requires a pre-sample preparation, where leukocyte nuclei are isolated from whole-blood and used as starting material for gDNA extraction.

Figure 11. Nuclei pellet.

For the nuclei isolation, fresh whole-blood from each dog was divided into several aliquots of 2-5 ml in 50 ml Falcon tubes (*Figure 10 and Table 3*). Each blood aliquot was treated in the following manner: a volume of ice-cold Buffer C1 (1.28 M sucrose; 40 mM Tris-Cl, pH 7.5; 20 mM MgCl₂; 4% Triton X-100) and 3 volumes of ice-cold distilled water were added, followed by a 10 minutes ice incubation. The lysed blood was then centrifuged in a swing-out rotor at 4 °C for 15 min at 1,300 x g and the resulting supernatant was discarded, leaving a pink nuclei pellet at the bottom of the tube.

To wash the nuclei pellet, 1 ml of ice-cold Buffer C1 and 3 ml of ice-cold distilled water were added, mixed by vertexing, and then centrifuged at 4 °C for 15 min at 1,300 x g. The supernatant was removed and the whole wash process was repeated until the pellet turned white (*Figure 11*).

The nuclei were stored at -20 °C until required for DNA extraction. All reagents used in this protocol are part of Qiagen's Genomic DNA Buffer Set (Qiagen, Hilden, Germany).

Table 3. Nuclei extraction sample list.

Dog ID	Breed	Whole-blood volume
LAB1_1	Labrador Retriever	3 ml

¹Nuclei extraction performed 15 days after blood draw.

QIAGEN Genomic-tip 100/G: HMW-gDNA extraction (O)

A total of 9 samples (*Table 4*) were processed with Qiagen's Genomic-tip 100/G following the manufacturer's instructions, which are described below.

DNA was extracted by using nuclei as starting material. The nuclei were lysed and digested by adding 5 ml of Buffer G2 (800 mM guanidine HCl; 30 mM Tris-Cl, pH 8.0; 30 mM EDTA, pH 8.0; 5% Tween-20; 0.5% Triton X-100), 95 µl of proteinase K, and incubated for 60 min at 50 °C. Thereafter a Genomic-tip was placed on top of a 50 ml Falcon tube and equilibrated with 4 ml of Buffer QBT (750 mM NaCl; 50 mM MOPS, pH 7.0; 15% isopropanol; 0.15% Triton X-100) (*Figure 12*). The lysed product was loaded into the Genomic-tip and left to drain completely by gravity flow. Next, two washes of 7.5 ml of Buffer QC (1.0 M NaCl; 50 mM MOPS, pH 7.0; 15% isopropanol) were applied. The Genomic-tip was placed on top of a new 15 ml Falcon tube and the gDNA was eluted by adding 5 ml of pre-warmed (50 °C) Buffer QF (1.25 M NaCl; 50 mM Tris-Cl, pH 8.5; 15% isopropanol).

DNA was precipitated by adding 3.5 ml of RT isopropanol and then pelleted at $>5,000 \times g$ ($\sim 7,000 \times g$) for 15 min at 4 °C. After removing the isopropanol supernatant, two washes of 2 ml of cold 70% ethanol with centrifugations at $>5,000 \times g$ ($\sim 7,000 \times g$) for 10 min at 4 °C were performed. Finally, the DNA pellet was dried at RT for 10 min, resuspended in a suitable buffer (e.g. TE, pH 8.0; nuclease-free water; or 10 mM Tris-HCl, pH 8.0), and dissolved at 55 °C for 2 hours.

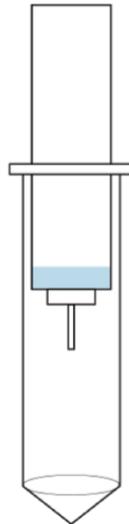

Figure 12. Genomic-tip 100/G extraction setup (Qiagen, Hilden, Germany).

QIAGEN Genomic-tip 100/G: HMW-gDNA extraction modified version (MV)

The original protocol does not include an RNase treatment, wherefore this was added prior to the digestion step with proteinase K. For every 5 ml of G2 Digestion Buffer, 10 μ l of RNase A (100 mg/ml) were added, followed by a 30 min incubation at 37 °C. Additionally, to prevent clogging the Genomic-tip by sample overloading, a two-Genomic-tip per sample system was implemented. A list of the samples extracted using this protocol can be found in *Table 4*.

Table 4. QIAGEN Genomic-tip 100/G sample list. O = Original protocol; MV = Modified Version.

2.2.3 Fire Monkey

RevoluGen's Fire Monkey is a mini-column-based protocol with the distinctive feature of including a size selection step that purifies long-fragments and removes fragments smaller than 10 kbp (RevoluGen, Berkshire, UK). Two samples (DSF1_1 and GOH1_1) were tested using this protocol and the nuclei isolated with Qiagen's Genomic DNA Buffer Set were used as starting material.

Fire Monkey's lysis and digestion steps were carried out by adding 300 µl of LSDNA, and 20 µl of proteinase K (10 mg/ml) to the nuclei pellet. After an incubation of 20 min at 56 °C, 350 µl of BS Buffer and 400 µl of 75% isopropanol were added, and the tube was carefully mixed. A 600 µl aliquot of the sample was pipetted into a spin column and centrifuged at 8,000 rpm for 1 min. The remaining sample was added to the same spin column and centrifuged at 8,000 rpm for 1 min. Next, 500 µl of WS Buffer were added and centrifuged at 8,000 rpm for 1 min. A wash with 500 µl of 90% ethanol was performed with a subsequent centrifugation at 14,000 rpm for 3 min, followed by an additional 1 min centrifugation step to prevent ethanol carryover. Then, the spin column was transferred to a pre-warmed Eppendorf tube, and 100 µl of pre-warmed (80 °C) EB Buffer were added. The tube was incubated at 80 °C for 1 min and then centrifuged at 4,000 rpm for 2 min. The resulting eluate, which contains the smaller DNA fragments, was discarded as it would not be used for sequencing. Once again, the spin column was transferred into a new pre-warmed Eppendorf tube, 100 µl of pre-warmed EB Buffer were added, the tube was incubated at 80 °C for 1 min, and centrifuged at 4,000 rpm for 2 min. The resulting eluate was kept for downstream applications.

2.2.4 Phenol-Chloroform

Phenol-Chloroform extraction is the only tested method that does not come as a kit. The protocol used in this study was developed by Jain *et al.* (2018), which is a modified version of the original protocol developed by Sambrook and Russell (2001). The samples extracted with this method are listed in *Table 5*, and the nuclei extracted with Qiagen's Genomic DNA Buffer Set were used as starting material.

In their protocol, Jain *et al.* (2018) use TLB (100 mM NaCl; 10 mM Tris-Cl, pH 8.0; 25 mM EDTA, pH 8.0; 0.5% SDS; 20 µg/ml Qiagen RNase A) as digestion buffer. However, this reagent was unavailable during the testing phase of this project, therefore, Qiagen's Digestion Buffer G2 was used as replacement.

Firstly, the nuclei pellet was lysed and digested using 5 ml of Qiagen's Buffer G2 mixed with 10 µl of RNase A (100 mg/ml). The mixture was incubated for 30 min at 37 °C, and then 95 µl of proteinase K were added, followed by an incubation of 60 min at 50 °C. A 1x volume of TE-Saturated phenol was added and the tube was manually mixed by constant inversion for 10 min. Then, the mixture was centrifuged at 4,500 rpm for 10 min and the aqueous phase was carefully removed and transferred into a new tube.

A 0.5x volume of TE-Saturated phenol and 0.5x Chloroform-Isoamyl Alcohol (24:1) were pipetted into the tube and then mixed manually for 10 min. Centrifugation was carried out at 4,500 rpm for 10 min and the aqueous phase was transferred into a clean tube. Next, 2M of Ammonium Acetate and 2x volumes of ice-cold 96% ethanol were added. Once the DNA pellet was visible, it was spooled with a glass rod and submerged in a 70% ethanol wash, lightly dried, and resuspended in 10 mM Tris-HCl pH 8.0 Buffer.

Table 5. Phenol-Chloroform protocol test samples. Samples LAB3_4 and LAB3_5 were extracted using 1.5 ml Eppendorf tubes. The remaining samples were extracted using 50 ml Falcon tubes.

Dog ID	Breed	Whole-blood volume
LAB1_3	Labrador Retriever	3 ml
LAB1_4	Labrador Retriever	3 ml
LAB2_1	Labrador Retriever	3.9 ml
LAB3_1	Labrador Retriever	5 ml
LAB3_3	Labrador Retriever	3 ml
LAB3_4	Labrador Retriever	500 µl
LAB3_5	Labrador Retriever	500 µl

2.3 DNA Quality Control

The quality and concentration of all samples were assessed using NanoDrop (Thermo Scientific NanoDrop 8000 Spectrophotometer V2.3.2) and Qubit® dsDNA BR assay (Invitrogen Qubit® 2.0 Fluorometer) respectively. Any sample with an absorbance ratio of ~ 1.8 for $A_{260/280}$ and ~ 2.0 - 2.2 for $A_{260/230}$ was considered of good quality.

Gel electrophoresis was carried out to evaluate fragment length and level of DNA degradation. The agarose concentration used was 0.5% and 1 μ l of HMW-DNA sample was loaded in each well. All gels were run at 30 V for 2 hours.

2.4 DNA Purification and Size Selection

2.4.1 AMPure XP Purification

For those samples that passed quality control, an additional purification step with Agencourt AMPure XP beads was performed (Beckman Coulter, IN, USA). The protocol followed was developed by Brandt (2019), and it also served as a pre-size selection step as it filters out fragments smaller than 100 bp.

To a 70 μ l volume of DNA, 20 μ l of nuclease-free water and 45 μ l of AMPure XP beads were added. The mix was resuspended by gently flicking, incubated at RT for 10 min, spun down with a microcentrifuge, and placed in a magnetic rack to pellet the beads. Without disturbing the pellet, 150 μ l of 80% ethanol were added and removed immediately. This step was repeated twice. The tube was taken from the rack, spun down, and placed again in the magnetic rack. Any trace of ethanol was pipetted out with a 10 μ l pipette tip. Following, 30 μ l of nuclease-free water were added, and the beads were resuspended by gentle flicking. After a 10 min incubation at RT, the tube was placed in the magnetic rack until the beads were pelleted. The supernatant containing the DNA was retrieved and placed in a new Eppendorf tube.

2.4.2 Circulomics Size Selection

Size selection was performed using Circulomics' Short Read Eliminator Kit (Circulomics, MD, USA). This kit eliminates fragments shorter than 10 kbp, favouring the sequencing of long-reads.

For this protocol, 60 μ l of DNA with a concentration of 150 ng/ μ l were placed in a LoBind Eppendorf tube, and 60 μ l of Buffer SRE were added. The tube was mixed gently and centrifuged at 10,000 x g for 30 min. The supernatant was

removed taking care of not disturbing the pellet. To wash the pellet, 200 μ l of 70% ethanol were added and the tube was centrifuged at 10,000 x g for 2 min. This wash step was performed twice. The DNA was resuspended in 100 μ l of EB Buffer and incubated for an hour at 50 °C.

2.4.3 Needle Shearing

To test the effects of DNA fragmentation on the ONT platform, needle shearing was performed on sample DSF1_2. This was done by passing the sample 3 to 4 times through a 27-gauge needle prior library preparation.

2.5 Library Preparation and Sequencing

All sequencing runs were performed using an ONT's MinION device (MIN-101B) and R9.4.1 flow cells (FLO-MIN106D) (*Figure 13*).

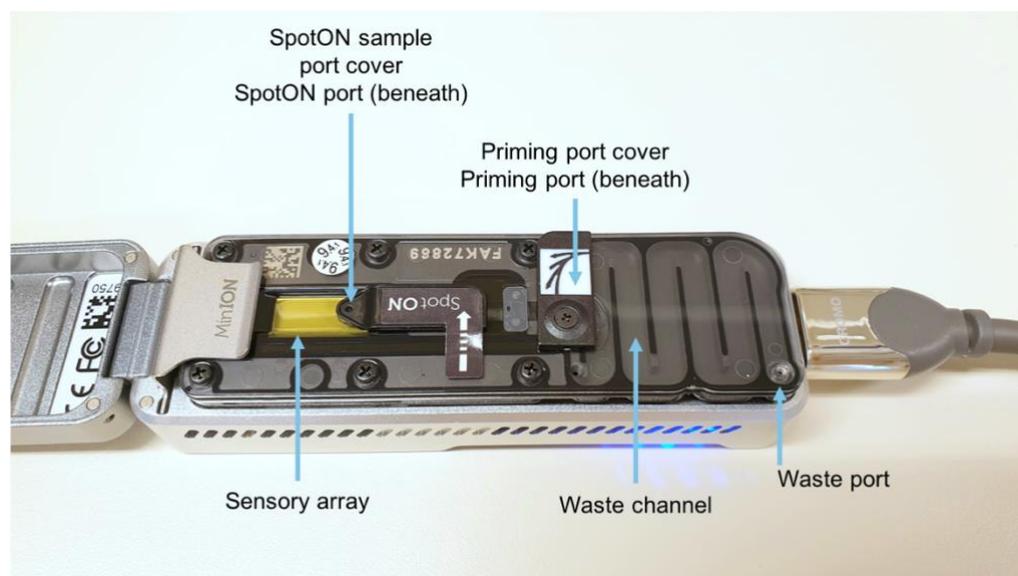

Figure 13. MinION sequencing device and flow cell components.

For library preparation, three ONT kits were tested: Ligation Sequencing Kit (SQK-LSK109), Rapid Kit (SQK-RAD004), and the Rapid Barcoding Kit (SQK-RBK004).

2.5.1 Ligation Sequencing Kit (SQK-LSK109)

The Ligation Sequencing Kit (SQK-LSK109) was the primary kit used throughout this project. From the various protocols that have been standardized to be used with this kit, the basic protocol '1D Genomic DNA by Ligation (SQK-LSK109)' was selected (ONT, Oxford, UK). Additionally, a third-party protocol developed by Quick (2018), as well as a final protocol that combines the strengths of ONT's and Quick's protocols were tested.

SQK-LSK109: 1D gDNA by Ligation (LSK109)

The library was prepared as per manufacturer's instructions with the following modifications: to avoid an additional tube-transfer that could further increase DNA shearing, the incubation for DNA repair, end-prep, and adapter ligation was performed not on a thermal cycler, which requires a sample transfer to 0.2 ml tubes, but on a block heater suited for 1.5 ml Eppendorf tubes. For the clean-up step that follows the adapter ligation, the Long Fragment Buffer (LFB) was used. The full protocol is described below.

The DNA input was prepared by transferring 200 fmol (~2µg) of gDNA into a LoBind tube and adjusting the volume to 47 µl with nuclease-free water. DNA repair and end-prep were performed by adding 1 µl of DNA CS, 3.5 µl of NEBNext FFPE DNA Repair Buffer, 2 µl of NEBNext FFPE DNA Repair Mix, 3.5 µl of NEBNext Ultra™ II End-prep reaction buffer, and 3 µl of NEBNext Ultra™ II End-prep enzyme mix to the input DNA and incubating it for 5 min at RT, and 5 min at 65 °C in a block heater. A volume of 60 µl of AMPure XP beads were added to the mixture, followed by an incubation of 5 min at RT. The mixture was washed twice with 200 µl of freshly prepared 70% ethanol and eluted in 61 µl of nuclease-free water.

Adapter ligation was performed by adding 25 µl of Ligation Buffer (LNB), 10 µl of NEBNext Quick T4 DNA Ligase, and 5 µl of Adapter Mix (AMX). The tube was mixed gently by flicking and incubated at RT for 10 min. A second clean-up step was carried out by adding 40 µl of AMPure XP beads, incubating for 5 min at RT, and washing the mixture twice with 250 µl of LFB. The washed beads were resuspended in 15 µl of Elution Buffer (EB), incubated for 10 min at RT, and pelleted in a magnetic rack. The supernatant (library) was retrieved and transferred into a new tube. Then, the library was prepared for loading by adding 37.5 µl of Sequencing Buffer (SQB) and 25.5 µl of Loading Beads (LB).

The MinION flow cell was primed by loading 800 µl of priming mix (30 µl of Flush Tether FLT and 1 tube of Flush Buffer FLB) into the priming port, and letting it incubate for 5 min. Next, the SpotON port was opened and additional 200 µl of

priming mix were added into the priming port. The sample was loaded in a drop-wise fashion with a P1000 pipette into the SpotON port (*Figure 13*).

SQK-LSK109: One-pot ligation protocol for Oxford Nanopore libraries (One-pot)

The One-pot library was prepared following Quick's (2018) instructions. This protocol uses an older version of the ligation kit (SQK-LSK108), therefore some modifications needed to be made. Firstly, the incubation time for the DNA repair and end-prep reaction was extended from 10 min to 15 min. Also, the volumes of the reagents used for the ligation step were modified to 5 μ l of AMX, 33 μ l of NEBNext® Ultra™ II Ligation Master Mix, and 1 μ l of NEBNext® Ligation Enhancer. For the clean-up step, 30 μ l of AMPure XP beads were used, and the washes were performed using 250 μ l of LFB. The reagents and volumes used for the final library preparation step were also modified to 37.5 μ l of SQB, 25.5 μ l of LB, and 12 μ l of library. The full version of this protocol is described below.

Approximately 200 fmol of DNA were transferred into an LoBind Eppendorf tube and the volume was adjusted to 24 μ l with nuclease-free water. For the DNA repair and end-prep 1.75 μ l of FFPE DNA Repair Buffer, 1 μ l of FFPE DNA Repair Mix, 1.75 μ l of Ultra™ II End-prep Reaction Buffer, and 1.5 μ l of Ultra™ II End-prep Enzyme Mix were added and incubated for 15 min at RT, and 15 min at 65 °C in a block heater.

Thereafter, adapter ligation was performed by adding 5 μ l of AMX, 33 μ l of Ultra™ II Ligation Master Mix, and 1 μ l of Ligation Enhancer. The mixture was flicked gently and incubated for 20 min at RT. After that, the sample was cleaned by adding 30 μ l of AMPure XP beads, incubating at RT for 10 min, pelleting the beads in a magnetic rack, and washing the mixture twice with 250 μ l of LFB. The beads were eluted in 12 μ l of EB, incubated for 10 min at RT, and pelleted in the magnetic rack. The supernatant was recovered and transferred into a new tube and placed on ice. Finally, the library was prepared for loading by adding 37.5 μ l of SQB and 25.5 μ l of LB and mixing gently by tapping the tube. The library was loaded into a primed flow cell through the SpotON port in a drop-wise fashion.

SQK-LSK109: Modified version (LSK109_{mv})

For the LSK109_{mv}, the library was prepared using a combined protocol that follows the instructions of the LSK109 protocol with the enzyme incubation times of the One-pot protocol. Therefore, instead of 5 minutes, 15 minutes of incubation time for the DNA repair, end-prep, and ligation steps were applied.

2.5.2 Rapid Sequencing Kit (SQK-RAD004)

The Rapid Sequencing Kit is one of ONT's fastest library preparation kits (circa 10 minutes). Unlike the SQK-LSK109 and SQK-RBK004 kits that were purchased at the start of this project, the SQK-RAD004 kit was acquired the prior year (2018). All SQK-RAD004 libraries were prepared following the manufacturer's instructions, which are described below (ONT, Oxford, UK).

In a clean 1.5 ml tube, 400 ng of gDNA were transferred and adjusted to a volume of 7.5 μ l with nuclease-free water. After this, 2.5 μ l of Fragmentation Mix (FRA) were added, and the tube was mixed by flicking and incubated for 1 min at 30 °C and 1 min at 80 °C. For the adapter attachment, 1 μ l of Rapid Adapter (RAP) was pipetted into the tube followed by a 5 min incubation at RT. The library was prepared for loading by adding 34 μ l of SQB, 25.5 μ l of LB, and 4.5 μ l of nuclease-free water. The library was loaded into the SpotON port of a pre-primed flow cell in a drop-wise fashion.

2.5.3 Rapid Barcoding Kit (SQK-RBK004)

The SQK-RBK004 protocol follows the same instructions as those of SQK-RAD004, with the exception that there is a barcoding step instead of a fragmentation step with FRA buffer. The sample barcoding was performed as follows: 2.5 μ l of Fragmentation Mix (RB) with a barcode from 1 to 12 were added to the input DNA and then incubated at 30 °C for 1 min and at 80 °C for 1 min. This kit was used when samples needed to be loaded into a flow cell that had been previously used with another individual's DNA.

2.6 ONT Flow Cell Wash and Nuclease Flush

Each flow cell was cleaned and reused at least once. After every run, the flow cell was washed utilizing the Flow Cell Wash Kit (EXP-WSH002) and stored at 4 °C until its next use.

Before starting a new run with a used flow cell, a nuclease flush was performed to unblock the pores that might be clogged with leftover DNA. This was done by mixing 290 μ l of Buffer A (300 mM KCl; 2 mM CaCl₂; 10 mM MgCl₂; 15 mM HEPES, pH 8.0) and 10 μ l of DNase I and loading the mixture through the flow cell's priming port. After an incubation period of \geq 1 hour at RT, the flow cell was primed, and a new sample was loaded.

2.7 Data acquisition and analysis

The experiments were run using version 3.1.19 of ONT's MinKNOW™ software on Ubuntu 16.04. Summaries of pore and channel performance, output quantity, and read length distribution were collected as .pdf files at the beginning and end of each run for quality assessment and troubleshooting purposes.

Basecalling was thereafter applied to the obtained raw data using Guppy version 3.0.3. For those samples that were barcoded using the SQK-RBK004 kit, a demultiplex step was added.

The quality control for each run was performed using an R script developed by ONT: "Nanopore_SumStatQC_Tutorial.Rmd." (ONT, 2019e). This script processes the summary text-file created by Guppy and generates a .pdf report containing key metrics, basic statistics, and sequencing performance visualizations (*Figure 14*).

All the basecalled data was concatenated into a single collection per individual and then mapped against the dog reference genome CanFam3.1 using the mapping program MiniMap2 v.2.16, which generated .sam and .bam output files. Thereafter, the SAMtools application was used to calculate basic statistics (e.g. number of reads, average read length, longest read, shortest read, and mean read length) and average coverage.

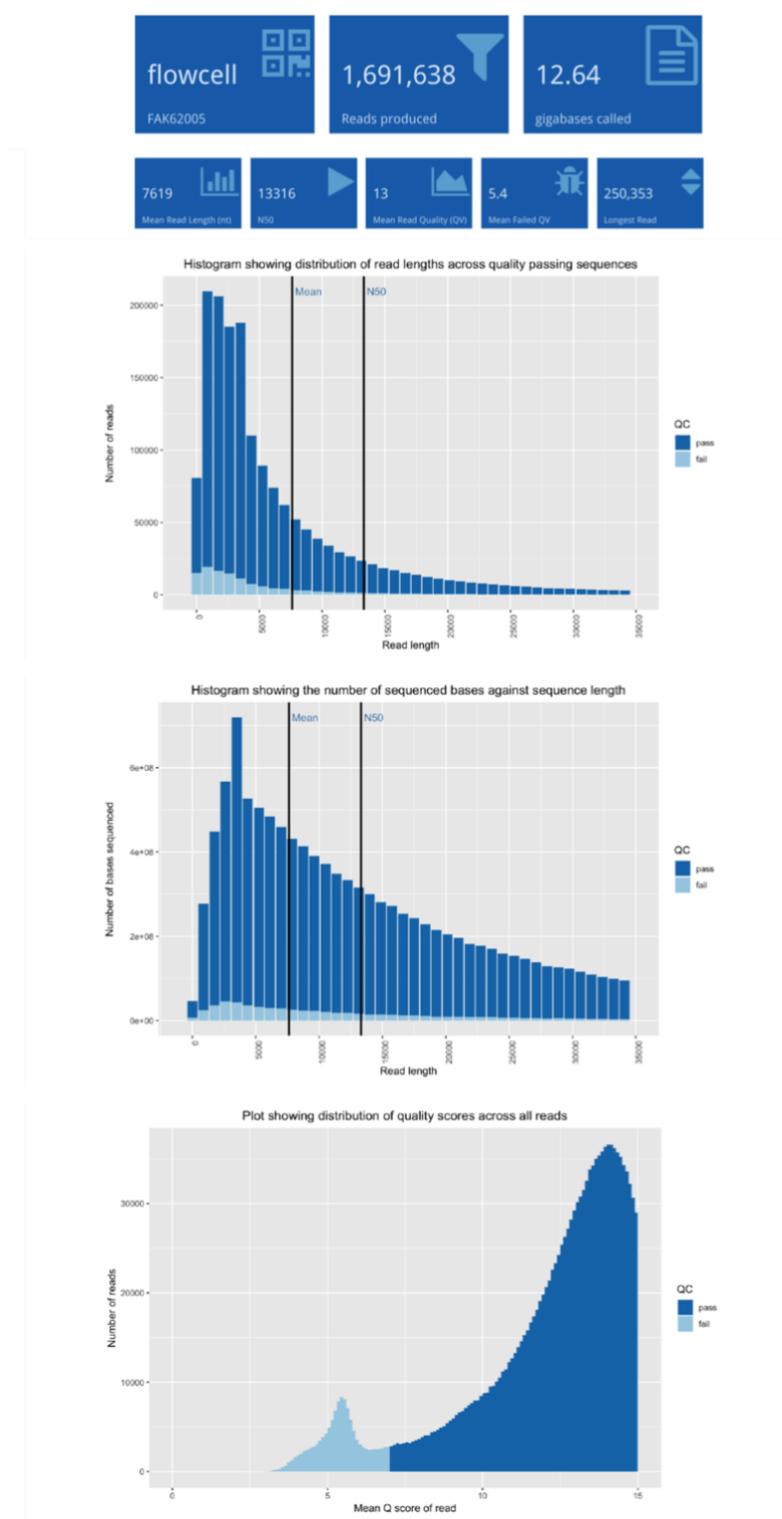

Figure 14. Example of output generated by ONT's R script for run quality control.

Finally, to have a better understanding of the power of long-reads, a portion of the canine MHC region, also known as dog leukocyte antigen (DLA), was extracted as a .bam file, mapped against the CanFam3.1 reference genome, and visualized using the Integrative Genomic Viewer (IGV) application (Robinson *et al.*, 2011). The selected region was the MHC class II DLA-DRB gene (12:2,151,409-2,164,562).

A complete list of the software used in this project and their references has been included in Appendix 2.

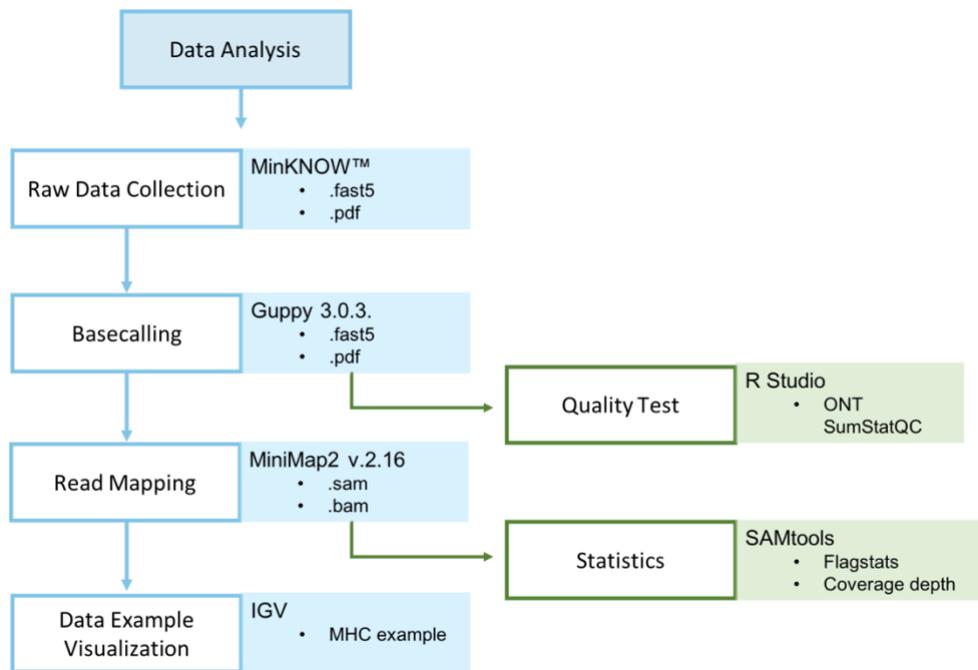

Figure 15. Data analysis workflow.

3 Results and Discussion

3.1 HMW-DNA Extraction

The isolation of high quality HMW-gDNA is a crucial step for obtaining high quality long-read data, therefore, finding a suitable DNA extraction method was one of the most important and challenging tasks of this study (Mayjonade *et al.*, 2017; Gong *et al.*, 2019).

Four extraction methods were tested using canine whole-blood and leukocyte nuclei as starting material to determine which one is the most suitable for Oxford Nanopore sequencing. Four key metrics were utilized in this assessment: yield, final concentration, average fragment length, and DNA purity determined by $A_{260/280}$ and $A_{260/230}$ absorbance ratios.

The results obtained, which have been compiled in *Table 6*, reveal that Qiagen's MagAttract® protocol produces insufficient total yield and volume for carrying out more than two nanopore sequencing runs per sample, reducing the total amount of data that can be gathered from a single extraction. Samples extracted with Fire Monkey presented some column-clogging issues and fragmentation, with a comparatively low mean read length of 3,572 bp (*Figure 22 and Table 10*). The attempts at extracting DNA following the Phenol-Chloroform protocol were unsuccessful (*Table 6*). It is suspected that this was due to a low pH environment, which pulls the nucleic acids into the phenolic phase (organic phase), and the presence of guanidine HCl in the lysis buffer, a salt that is used for separating gDNA from RNA in RNA extraction protocols (Xu *et al.*, 2011, 2019). There is, however, no conclusive evidence to support this theory; further testing would be required to reach a verdict.

After comparing the metrics for total DNA yield, concentration, average fragment length, and DNA purity, it was determined that the modified version of QIAGEN Genomic-tip 100/G protocol (MV) yielded the best results. All samples

maintained an absorption ratio within or close to the desired range ($A_{260/280} \sim 1.8$, $A_{260/230}$ 2.0-2.2), and the concentration and total DNA yield of the final product was enough for preparing from 5 to 10 libraries, thereby increasing the amount of data generated per extraction (*Table 6 and Table 10*). Additionally, the average fragment size achieved with this protocol was greater than 20 kbp, a size comparable to that of MagAttract® and Fire Monkey, as revealed by gel electrophoresis (*Figure 16*).

Two key factors that might have contributed to the success of this method were the use of a two-Genomic-tip system, and the resuspension and storage of DNA in 10 mM Tris-HCl pH 8.0 instead of TE buffer (25 mM Tris pH 8.0, 1 mM EDTA) or nuclease-free water (*Table 6*).

The two-Genomic-tip system was implemented as a solution to the issue of tip clogging due to sample overloading, which occurred on a number of occasions, with the most extreme case being sample GOH1_2 which required to be manually pumped out of the Genomic-tip by positive pressure. This problem arose despite all samples having an initial whole-blood volume of 2-4 ml, which agrees with Qiagen's recommendations of input material for the Genomic-tip 100/G (1-5 ml). The result of using this system was a faster extraction, with two DNA aliquots per sample that could either be kept separated or merged in a single Eppendorf tube. Although successful extractions were obtained with this method, a larger Genomic-tip such as the 500/G would potentially minimize clogging and eliminate the need to use a double-tip configuration (Qiagen, Hilden, Germany).

Three different DNA storage buffers were tested throughout this project: TE buffer, 10 mM Tris-HCl pH 8.0, and nuclease-free water. From these buffers, 10 mM Tris-HCl pH 8.0 was found to be the most suitable. Its pH buffering properties prevent the environment from reaching an acidic state, which can cause DNA denaturation, and unlike TE buffer, it does not contain EDTA, a chelating agent that is known to cause interference in downstream applications due to its binding properties to metal ions, such as Mg^{2+} , which are cofactors needed for enzymatic catalysis (An *et al.*, 2014).

DNA pellets that were resuspended in nuclease-free water had higher levels of fragmentation and couldn't be fully homogenized (e.g. DSF1_2 and GOH1_2; *Table 6*). DNA is known to dissolve better in alkaline mediums such as TE or Tris-HCl pH 8.0, however nuclease-free water's pH is slightly acidic (pH 5-6) (Kim *et al.*, 2012; An *et al.*, 2014).

It is suspected that incomplete DNA resuspension and storage in water might have had a negative impact on DSF1_2 and GOH1_2, being these the only samples that had a large discrepancy between Qubit and NanoDrop measurements, which is an indicator for DNA degradation (*Table 6*).

NanoDrop works on the principle that nucleic acids absorb UV light at 260 nm, however this could become a problem since it cannot distinguish between dsDNA,

ssDNA and RNA, which means that it has a tendency to overestimate the presence of dsDNA. On the other hand, Qubit uses an intercalating dye that only produces a fluorescent signal if it is bound to the target of interest, in this case dsDNA (Georgiou and Papapostolou, 2006; Sedlackova *et al.*, 2013). This hypothesis is supported by the results obtained from the sequencing run statistics and quality control tests, which revealed that these samples were among the ones that had the lowest ‘mean read length’ and shortest ‘longest read’ (Table 10).

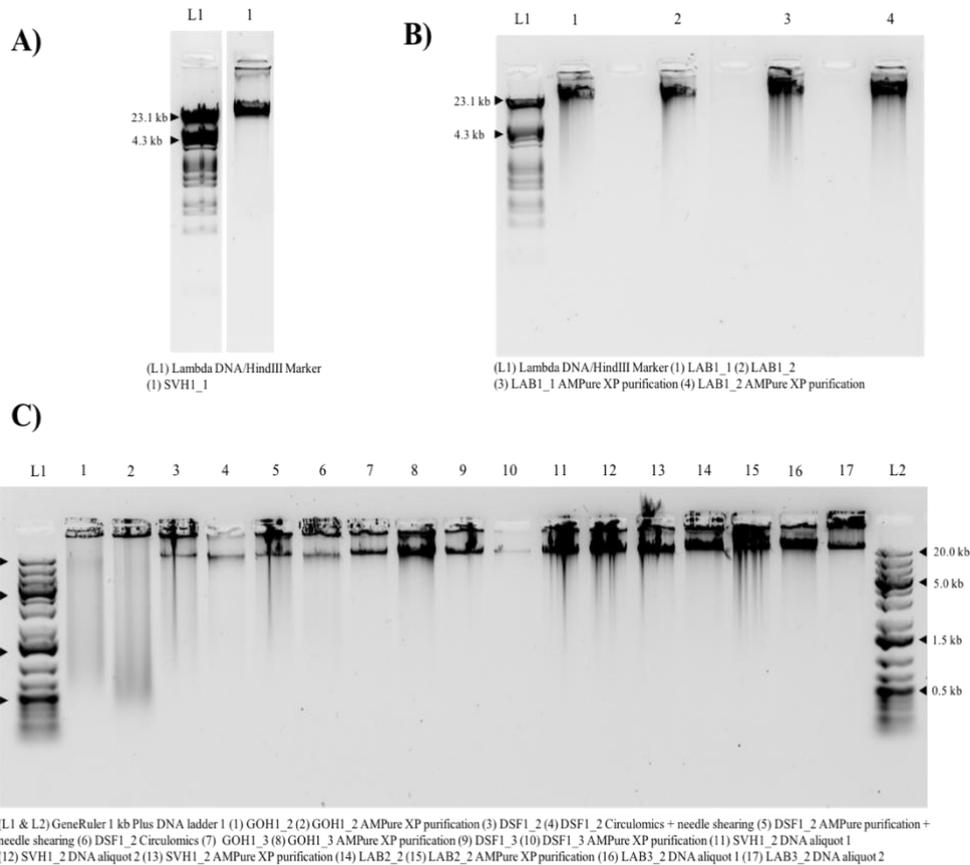

Figure 16. Electrophoresis results. All samples show an average fragment length of >20 kbp. A) Sample SVH1_1 extracted with MagAttract® MHW DNA Kit. B) Samples LAB1_1 and LAB1_2 extracted with QIAGEN Genomic-tip 100/G and purified using AMPure XP beads. C) All remaining samples that were extracted with QIAGEN Genomic-tip 100/G and the different purification and size selection treatments that were used for each sample (e.g. AMPure XP purification, Circulomics Short Read Elimination Kit, and needle shearing). Samples 1,2,3, and 5 had higher degree of fragmentation than others. Samples 11-15 had overloading issues due to high-DNA concentration.

Table 6. HMW-DNA extraction results.

Sample ID	Whole-blood input	Starting material	Storage buffer	Concentration (ng/μl)	Volume (μl)	Total DNA yield (μg)	A _{260/280}	A _{260/230}
<i>Protocol: QIAGEN Genomic-tip 100/G</i>

Storage buffers: 1) TE buffer (25 mM Tris pH 8.0; 1mM EDTA); 2) Tris-buffer (10 mM Tris-HCl pH 8.0); 3) NFW (nuclease-free water); 4) AE buffer (10 mM Tris-Cl; 0.5 mM EDTA pH 9.0); 5) EB buffer (10 mM Tris-Cl pH 8.5). * NanoDrop measurements due to Qubit failure.

Samples marked with bold letters followed the double-Genomic-tip system used in the modified version (MV) of QIAGEN Genomic-tip 100/G protocol.

3.2 Oxford Nanopore Sequencing: Protocol Optimization

A total of 21 Oxford Nanopore sequencing runs were carried out throughout this project: 14 were performed with the Ligation Sequencing kit (SQK-LSK109), 2 with the Rapid Sequencing kit (SQK-RAD004), and 5 with the Rapid Barcoding kit (RBK004). Of these 21 runs, three experienced technical failures and thus could not be included in the data analysis. A summarized version of the results obtained from each run is presented in *Table 10*.

3.2.1 ONT Library (SQK-LSK109)

The Ligation Sequencing Kit (SQK-LSK109) was the main kit used for library preparation in this study, selected due to its high throughput and yield (ONT, Oxford, UK). Because at the time of this study only a limited amount of publications had been made on the use of Oxford Nanopore for eukaryotic gDNA sequencing, more specifically mammalian gDNA, several tests and optimizations were required in order to create a successful library.

SQK-LSK109 sequencing optimization

One of the main challenges encountered was the high pore-loss rate that resulted in a decrease of data output and premature stop of the sequencing runs. Pore-loss reduced the expected run time from 48 to an average of 20 hours, and the generated data averaged between 1-4 GB, with the exception of run 20 (*Figure 17 and Table 10*).

The pore-loss degree varied for every run, but its presence was consistent. According to ONT, the build-up of ‘inactive’ channels over time could indicate that there is an osmotic imbalance or contaminant carryover that has damaged the membrane of the flow cell (Ronan, 2018). An additional explanation proposed by the members of the ‘The Nanopore Community’ is the blockage of nanopore channels by long DNA fragments that have formed secondary structures (ONT, 2019c and f). By performing a DNase I treatment in used flow cells (see: methods; flow cell wash and nuclease flush), which resulted in an average increase from 235 to 830 active pores, it was concluded that DNA could be one of the primary causes of pore-loss. However, this does not discard that contaminant carryover might have an effect as well.

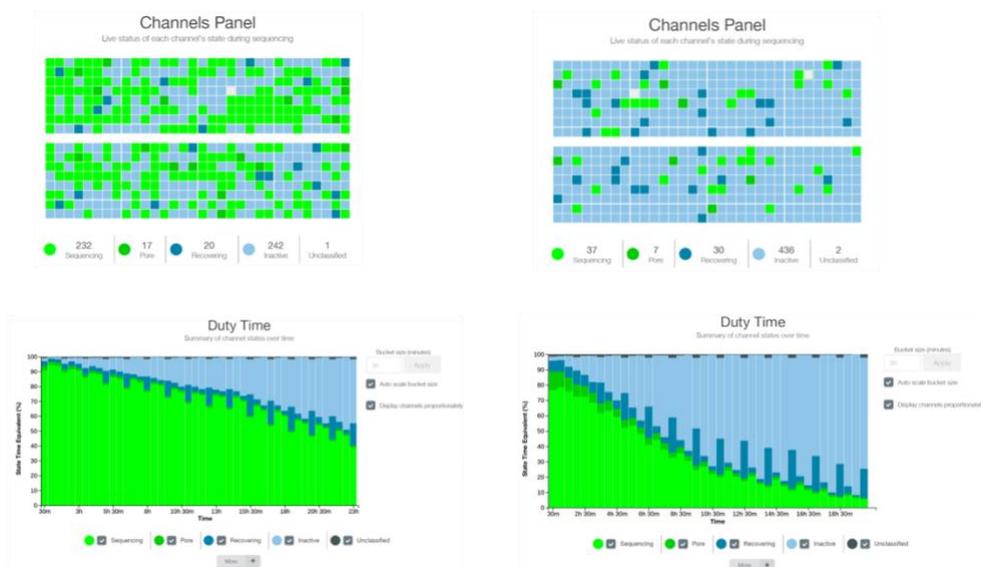

Figure 17. Example of pore-loss as an accumulation of ‘inactive pores’ (light blue). To the left there is an example of successful library that ran for 23 hours and still has available pores for sequencing (light green). To the right is an example of a library that has run for 23 hours and cannot continue due to pore-loss.

DNA fragmentation by needle shearing was tested in runs 6 and 8 to verify if by reducing the fragment size of the sample, the pore-blockage rate would decrease. No evident changes were observed (*Table 10*), possibly due to the tests being carried out in sample DSF1_2, which was later found to be of insufficient quality (see: results and discussion; HMW-DNA extraction), and thus the effect of shearing could not be recorded.

Although not as problematic as pore-loss, pore occupancy and final yield were other issues that warranted optimization (*Figure 18*). These issues were addressed by prolonging the enzyme incubation times used for DNA repair, end-prep, and adapter ligation with the objective of increasing the efficiency of adapter AMX ligation, and thus incrementing the successful translocation of the DNA strands through the nanopore. This adjustment was based on Quick’s One-pot protocol (2018) and the enzyme manufacturer’s recommendations (NEB, Ipswich, MA), and was included as part of the LSK109_{mv} protocol (see: methods). Although several tests were performed using this method, it was not possible to reach a definitive conclusion as many variables like sample quality, library loading input, and fragment size were also in play (*Table 10*). However, run 20, which produced the highest amount of data (14.06 Gbp) and had high pore occupancy, was processed using this method.

Furthermore, runs 1, 10, and 21, that were prepared with the LSK109_{mv} and One-pot protocols, had also acceptable data yields ranging from 4.7 Gbp to 6.11 Gbp. The only samples in this study that didn't benefit from this procedure were DSF1_2 and GOH1_2. Based on these observations, it is likely that prolonging enzyme incubation times could offer some benefit to pore occupancy, however in order to determine this, further experimentation would be required.

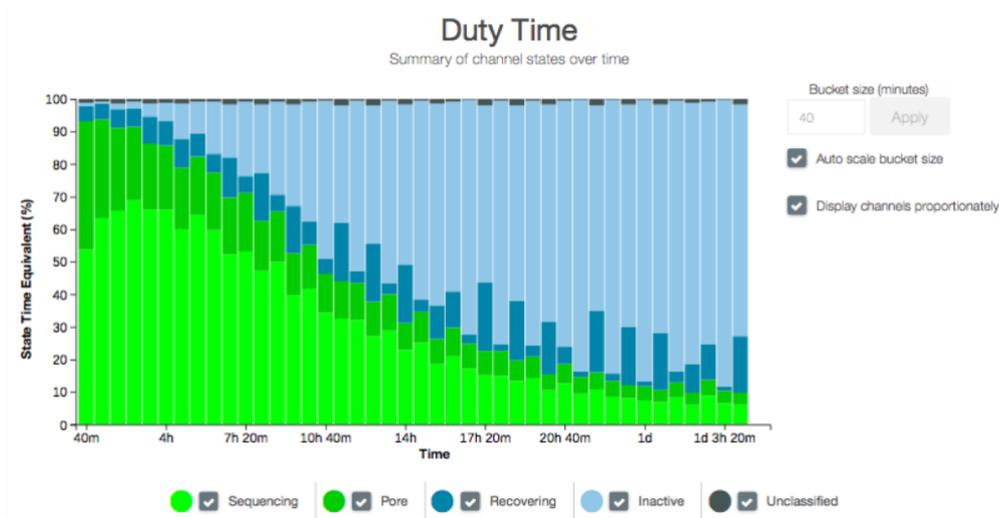

Figure 18. Example of low pore occupancy. The high ratio of ‘pore’ (dark green) to ‘sequencing’ (light green) means that the amount of DNA passing through the pores is very low.

Insufficient starting material may also be a detrimental factor for pore occupancy. For the SQK-LSK109 kit, ONT recommends an input mass of 1 µg of gDNA and to load no more than 600 ng of library into the flow cell (ONT, Oxford, UK). After analysing the performance of several libraries, it was concluded that loading more than the recommended threshold yielded better results and that pore occupancy improved greatly. This can be observed in *Table 10*, where the three experiments that produced the highest amount of data were loaded with > 600 ng of library (run 10, 12, and 20).

Selecting the appropriate enzymes for nanopore sequencing was also part of the optimization process for the SQK-LSK109 kit. The LSK109 and One-pot protocols are quite similar (see: methods), however a major discrepancy between these protocols is the use of different enzymes for adapter ligation. Although LSK109 recommends the use of NEBNext® Quick Ligation Module, the One-pot protocol utilizes the NEBNext® Ultra™ II Ligation Module.

According to the manufacturer, New England BioLabs, the main difference between these two enzymes is that the Ultra™ II Ligation Module has been

optimized to work with the NEBNext® Ultra™ II End Repair/dA-Tailing Module, a reagent used for end-prep in both protocols.

A comparison between both enzymes was carried out by testing each enzyme in both the LSK109 and One-pot protocols (*Table 7*). The results of this experiment revealed that the LSK109 protocol, along with the Quick Ligation Module, yielded the best results as it had a lower degree of post-library DNA loss and generated a larger amount of data.

Table 7. Comparison of ligation enzymes. Enzymes tested: NEBNext® Quick Ligation Module (QLM) and NEBNext® Ultra II™ Ligation Module (ULM). The library input refers to the amount of DNA used for library preparation, and the Seq. input is the amount of DNA loaded into the flow cell. The highlighted row belongs to the most successful run of this experiment.

Run No.	Sample ID	Library input	A _{260/280} / A _{260/230}	Seq. input	Library protocol	Enzyme tested	Reads produced	Gbp called	Mean read length	Longest read
10	DSF1_3	1.4 µg	1.87 / 2.25	1,097 ng	One-pot	QLM	405,347	6.11	15,437	196,239
11	DSF1_3	1.4 µg	1.87 / 2.25	648 ng	One-pot	ULM	225,595	3.51	16,089	237,452
12	DSF1_3	1.4 µg	1.87 / 2.25	714 ng	LSK109	QLM	578,829	7.34	13,144	202,707
13	DSF1_3	1.4 µg	1.87 / 2.25	594 ng	LSK109	ULM	291,017	4.38	15,428	198,328

Because long-reads were one of the main goals set for this project, pre-library size selection was performed utilizing the Circulomics Short Read Elimination kit to improve the read length of those samples that had a mean size distribution below 10 kbp.

It should be noted that, as this kit has an expected HMW-gDNA recovery of ~60% (Circulomics, Baltimore, MD), sample concentration and volume had to be taken into consideration, since having enough material for performing several sequencing runs per sample is imperative for generating an adequate amount of data for downstream analysis.

Because of this, only samples LAB1_1, DSF1_2, and SVH1_2 were size selected using Circulomics. By comparing the mean read length of non-size selected runs and Circulomics runs, it was concluded that this method was successful in enriching for long reads (*Figure 19 and Table 8*). Similar to previous experiments, sample DSF1_2 presented some issues that could be linked to the quality of the sample.

The drawback of this technique is that pore-loss rate is higher, and the amount of data generated is lower than that of a library prepared with shorter fragments (*Figure 19*).

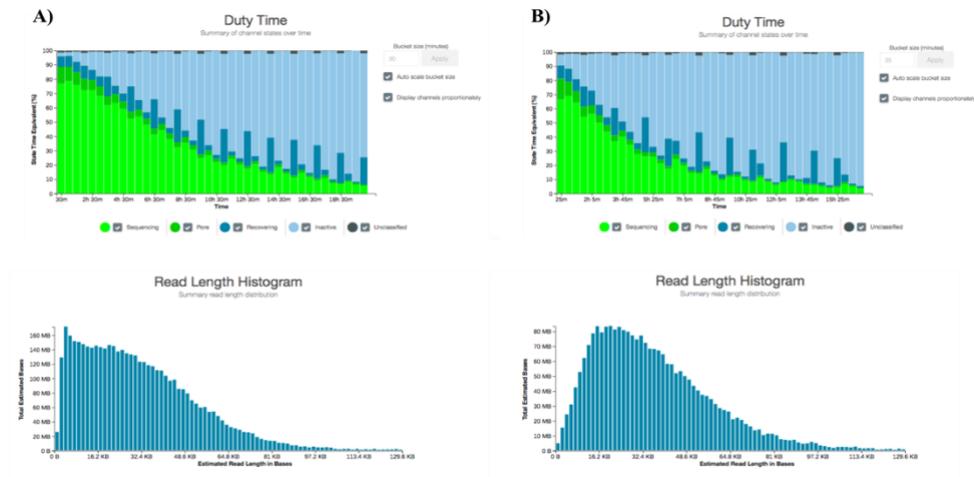

Figure 19. Circulomics size selection test. A) Run without size selection: regular pore-loss, mean read length leaning towards 15 kbp and 4.97 Gbp called. B) Run with Circulomics size selection: increased pore-loss, mean read length leaning towards 20 kbp, and 2.36 Gbp called.

Table 8. Comparison between Circulomics size selection and no size selection. Circulomics size selected samples had a greater mean read length than samples without size selection. On the other hand, non-size selected samples yielded a higher amount of data than size-selected samples.

Run no.	Dog ID	Mean read length	Raw Gbp	Size Selection
1	LAB1_1	15,039	4.7	-
2	LAB1_1	21,456	2.63	Circulomics
15	SVH_2	6,625	6.14	-
18	SVH1_2	10,605	3.46	Circulomics

SQK-LSK109 final results

From all the sequencing experiments that were carried out, run 20 had the best performance, producing a total of 14.06 Gbp of raw data in the span of 48 hours (*Figure 20*). The success of this run is attributed to the quality of the DNA ($A_{260/280}$ 1.80 and $A_{260/230}$ 2.28), the inclusion of a 15-minute incubation time for the enzymatic reactions during library preparation, and the high concentration of library loaded into the flow cell (1.2 μg). Additionally, the sample was slightly fragmented (mean read length of 7,619 bp) for unknown reasons, which may have contributed to the reduction in pore blockage, permitting the run to continue and generate data for 48 hours. These results are an improvement over the most recent human genome sequencing project of Bowden *et al.* (2019), in which an average of 5.0 Gbp of raw data per 48 hour run was obtained.

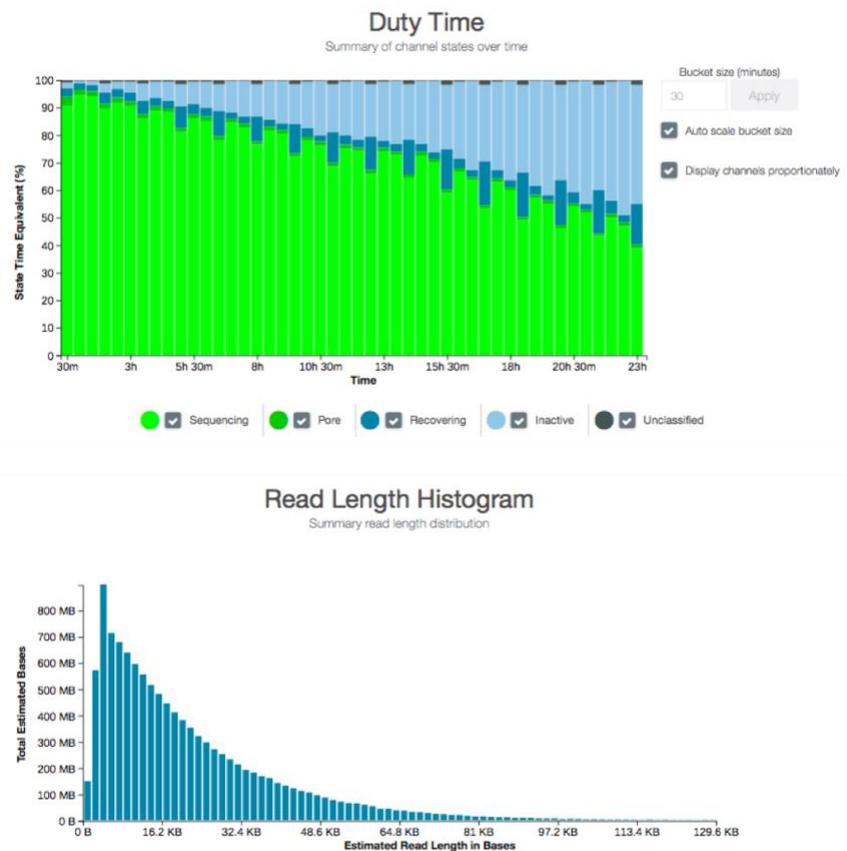

Figure 20. Run 20 final report after running for 48 h. Duty time shows low pore-loss and high pore-occupancy. The read length histogram indicates that the majority of the reads sequenced had a size below 16 kbp (mean read length: 7,619 bp).

On the other hand, the experiments that had the lowest performance (low data yield and average read length) were runs 6, 7, and 8, which were carried out using samples that were stored in nuclease-free water (*Table 6 and Table 10*). This supports the previously discussed issues concerning tip-blockage and water storage.

The highly degraded state of these samples is further confirmed by their low data yield, and by the read length histograms generated by MinKNOW™ (*Figure 21 and Table 10*). Based on these results, and considering that the AMX adapters that guide the DNA to the nanopore for sequencing only bind to dsDNA, it is suspected that the elevated concentrations of nucleic acids that were detected by NanoDrop came from ssDNA (ONT, Oxford, UK; Sedlackova *et al.*, 2013).

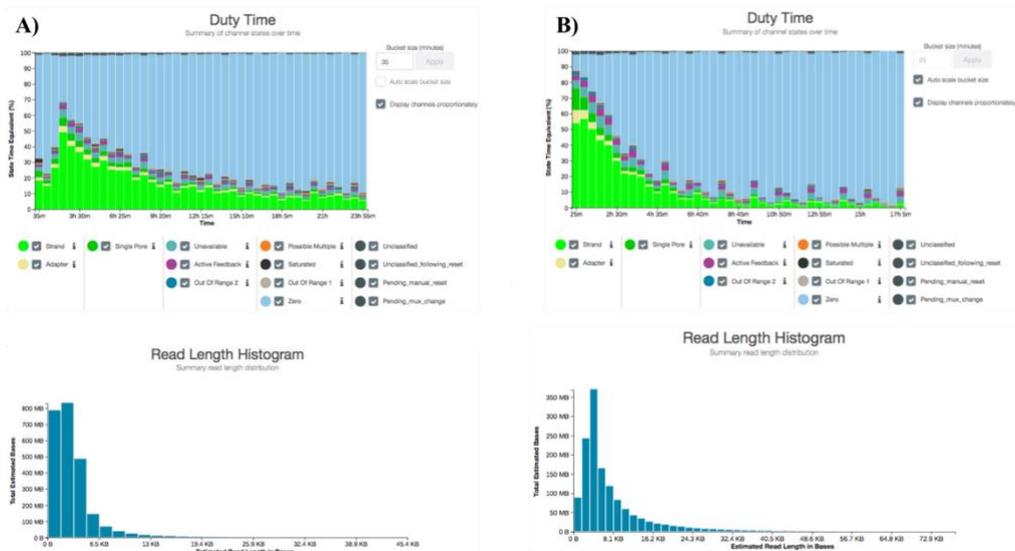

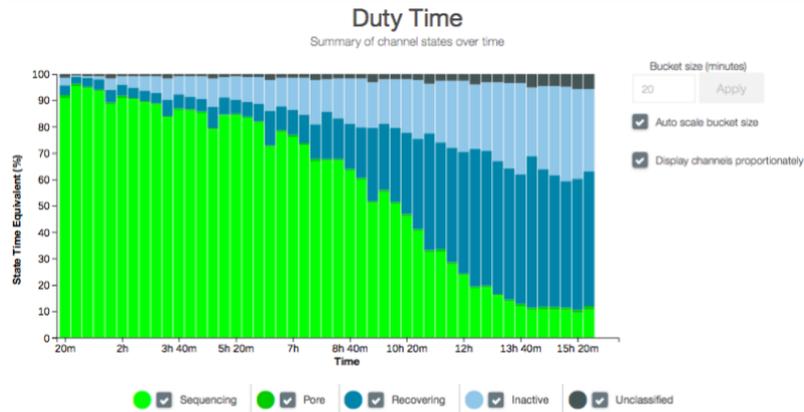

Figure 21. Run 7 and 8 final reports after a 20 h run. In both cases, duty time shows a rapid pore-loss and the read length histogram indicates that almost all the reads were around 6 kbp.

Despite generating an acceptable amount of data (4.31 Gbp), run3 also presented some issues related to fragmentation (mean read length of 3,572), which does not align with the long-read sequencing focus of this study (*Figure 22*).

Read Length Histogram
Summary read length distribution

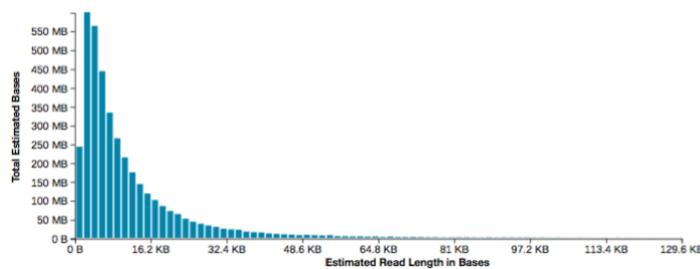

Figure 22. Run 3 results. This run was done in GOH1_1, the only sequenced sample that was extracted using RevoluGen’s FireMonkey kit. There was a sudden pore loss after 8 h of running and an accumulation of ‘recovering’ (light blue) and ‘inactive’ (dark blue) pores. The read length histogram also shows that the majority of the fragments had a size below 16 kbp.

3.2.2 ONT Library (SQK-RAD004 and SQK-RBK004)

Unlike SQK-LSK109 kit, SQK-RAD004 and SQK-RBK004 kits have been optimized for speed and convenience. Because these kits require little handling, longer reads can be achieved despite having a transposase-based fragmentation step (ONT, Oxford, UK). This feature has been exploited in various studies where achieving ultra-long reads is of high importance (O’Neil *et al.*, 2017; Jain *et al.*, 2018; Kono and Arakawa, 2019). However, for the purpose of this project, these kits were used mainly for increasing the amount of data per individual and for reusing old flow cells. No changes were made to these kit’s protocols and no optimization was required.

The used RAD004 kit, was purchased a year before the start of this study. It is possible that the reagents of the kit had loss effectiveness and therefore no conclusions can be drawn from the results obtained. On the other hand, the RBK004

kit was newly acquired and it was particularly useful when preparing a library that would be loaded in a flow cell that had been previously used with another individual's DNA. This kit's performance had an average of 2.66 Gbp of raw data per flow cell and 6,542 bp of average mean read length. However, these results should not be used for assessing this kit's overall performance since all tests were ran in recycled flow cells (*Table 10*).

3.2.3 Maximizing Flow Cell Utility

Performing a flow cell wash, followed by a nuclease flush before starting a second run, proved to be a successful way to maximise the utility of each flow cell and reduce costs. Of a total of 21 runs, 12 were performed with new flow cells and generated an average of 5.22 Gbp of raw data each. The remaining 9 were run in used flow cells, generating an average of 1.92 Gbp each (*Table 9*).

Whereas the average cost per Gbp obtained with new flow cells was \$192 USD, factoring in the savings from reusing flow cells brings the average cost down to \$158 USD; a difference of \$34 USD. In Appendix 3, a full breakdown of the cost of these calculations is included.

Although pore recovery differed from run to run (*Figure 23*), the average number of pores available for sequencing after a nuclease flush was 830 of a total of available 2048 pores.

Table 9. Flow cells use. Number of new and reused flow cells used per individual and total amount of data generated.

Dog ID	No. of new flow cells	Gbp obtained	No. of used flow cells	Gbp obtained
LAB1	2	7.33	0	0
LAB2	1	5.85	1	2.57
DSF1	5	22.12	2	1.64
GOH1	3	13.28	4	3.55
SVH1	1	14.06	2	9.60
Total	12	62.64	9	17.36

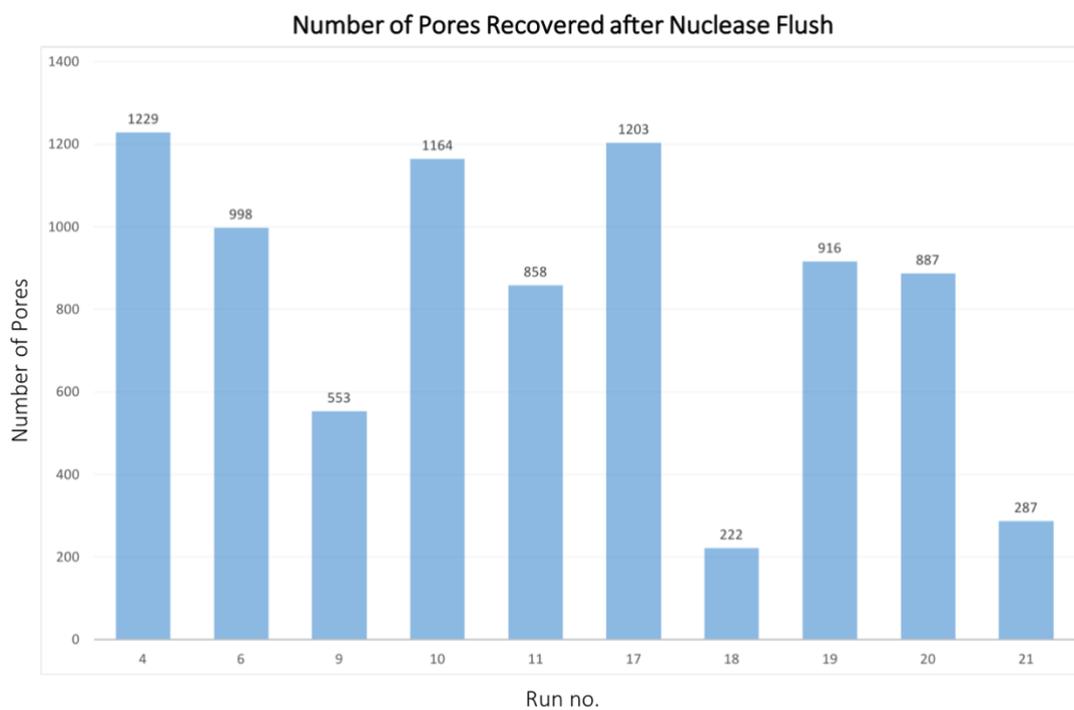

Figure 23. Pores recovered after nuclease flush. The number of pores corresponds to the total amount of pores that were available for sequencing at the start of a run with a used flow cell.

3.3 Final Results per Individual

The data obtained from each flow cell was merged per individual for further data analysis. This analysis revealed that the average data yield per individual was of 16 Gbp and that the coverage ranged between 3.1 to 9.23, with the average being 5.89. As expected, there was a consistent correlation between data yield and total coverage (*Table 11*) (Sims *et al.*, 2014; Pollard *et al.*, 2018).

The individual with the highest coverage and data yield was DSF1 (9.23x coverage), followed by SVH1 (7.55x coverage). Although these results are quite similar, DSF1 was sequenced using 7 flow cells, whereas SVH1 used only 3. This highlights the importance of developing a method that maximizes data output per run.

Table 11. Final results per individual. This table gathers all the relevant sequencing information per individual.

Dog ID	Average Coverage	No. Reads	Average read length	Longest read	Shortest read	Total Gbp
LAB1	3.73	470,236	18,247	221,455	3	7.33
LAB2	3.1	793,367	8,792	184,391	11	8.42
DSF1	9.23	2,099,348	11,631	237,452	3	23.76
GOH1	5.84	5,341,723	4,561	202,485	1	16.83
SVH1	7.55	2,501,471	8,292	250,353	4	23.66

3.3.1 Visualizing Long-Reads in the MHC Region

The mapping of the MHC class II DLA-DRB gene against the CanFam3.1 reference genome revealed several long reads that covered entire genes and spanned across intronic regions, thereby connecting neighbouring genes.

As *Figure 24* illustrates, the error and variation rates between the reference genome and the mapped reads is quite high. This is to be expected as raw long reads tend to have a higher error rate than short reads. Additional improvements can be made at later stages in the bioinformatics pipeline, and/or by using Illumina data for polishing, creating a hybrid assembly (Jansen *et al.*, 2017; Dhar *et al.*, 2019; Morrissey *et al.*, 2019).

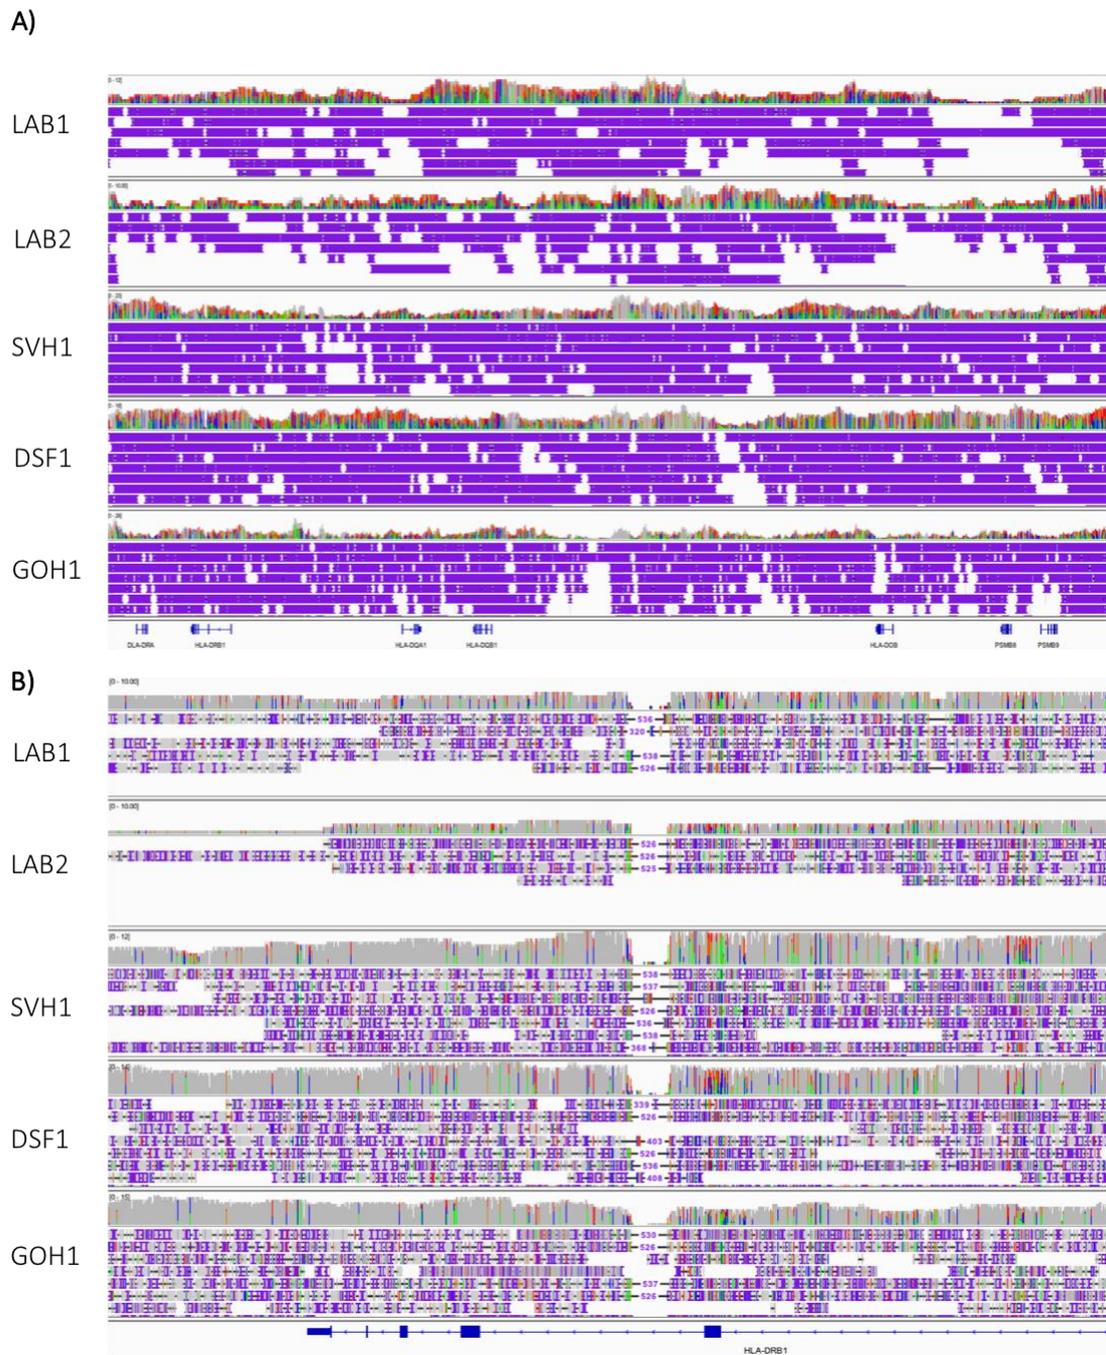

Figure 24. Sequenced reads mapped against CanFam3.1 reference genome. This region belongs to the MHC class II DLA-DRB gene (12:2,151,409-2,164,562). Discrepancies between the mapped reads and the reference genome are highlighted in purple, while matching areas are colored in gray. A) Zoom out version. Long reads can be seen covering entire genes. B) Close up version.

3.4 Conclusions

The principal takeaway of this study is that, drawbacks considered, Oxford Nanopore holds much potential for the type of work contemplated in this study.

The preestablished methods and protocols did require considerable adjustments in order to be applicable for the target species. After several test runs, a successful protocol was established, however further experimentation might result in a methodology with even greater results. Potential improvements include modifying the phenol-chloroform method for the successful extraction of HMW-gDNA, utilizing a larger Genomic-tip configuration, and increasing the enzyme incubation times during library preparation.

The final iteration of the protocol is described in continuation.

1. HMW-gDNA Extraction: QIAGEN Genomic-tip 100/G (MV) with double-tip system and DNA storage with Tris-HCl, pH 8.0
2. DNA Purification: AMPure XP purification
3. Size Selection: Circulomics size selection if desired
4. ONT Sequencing: SQK-LSK109 ligation protocol
 - i. Library input of 200 fmol of high-quality HMW-gDNA
 - ii. Repair and end-prep incubation time of ≥ 15 minutes
 - iii. Ligation incubation time of ≥ 15 minutes

For maximizing the utility of the flow cell, these optional steps are recommended:

1. Flow cell wash and storage at 4 °C until next run
2. Flow cell nuclease flush and incubation for ≥ 1 hour
3. Preparation of secondary library with RAD004 or SQK-RBK004 kit

Appendix 1

List of Consumables: HMW-DNA Extraction

Qiagen, Hilden, Germany

MagAttract® HMW DNA Kit (cat. no. 67563)

Kit Contents

MagAttract Suspension G

Buffer ATL

Buffer MB

Buffer MW1 (concentrate)

Buffer PE (concentrate)

Buffer AE

Proteinase K

RNase A (100 mg/ml)

Nuclease-free water

Equipment

Eppendorf tubes (1.5 ml)

Thermomixer

Magnetic rack

Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

Qiagen, Hilden, Germany

QIAGEN Genomic-tip 100/G Kit (cat. no. 10243)

Genomic DNA Buffer Set (cat. no. 19060)

Kit Contents

Composition

Genomic-tip 100/G

Buffer C1 1.28 M sucrose; 40 mM Tris-Cl, pH 7.5; 20 mM MgCl₂; 4% Triton X-100

Buffer G2 Digestion Buffer. 800 mM guanidine HCl; 30 mM Tris-Cl, pH 8.0; 30 mM EDTA, pH 8.0; 5% Tween-20; 0.5% Triton X-100

Buffer QBT Equilibration Buffer. 750 mM NaCl; 50 mM MOPS, pH 7.0; 15% isopropanol; 0.15% Triton X-100

Buffer QC Wash Buffer. 1.0 M NaCl; 50 mM MOPS, pH 7.0; 15% isopropanol

Buffer QF Elution Buffer. 1.25 M NaCl; 50 mM Tris-Cl, pH 8.5; 15% isopropanol

Proteinase K

Additional reagents
Distilled water
Ethanol 70%
Isopropanol
Proteinase K
RNase A (100 mg/ml)
Equipment
Heat block / water bath
Centrifuge (temperature control and capacity for >5000 x g velocity)
Pipettes and pipette tips P2, P10, P20, P100, P200, P1000
Starstedt (PP) Falcon tubes 50 ml, 15 ml

RevoluGen, Berkshire, UK

Fire Monkey Kit (<https://revolugen.co.uk/revolugens-dna-extraction-technologies/>)

Kit Contents
Spin-columns
Collection tubes (2 ml)
Lysis Solution DNA (LSDNA)
Binding Solution (BS)
Wash Solution (WS)
Elution Buffer (EB)
Additional reagents
Ethanol 96%
Isopropanol 75%
Proteinase K (10 mg/ml)
Equipment
Centrifuge
Pipettes and pipette tips P2, P10, P20, P100, P200, P1000
Thermomixer
Vortex

Jain *et al.* (2018)

Protocol: Ultra-long read sequencing protocol for RAD004 V.3

Protocols.io: [dx.doi.org/10.17504/protocols.io.mrxc57n](https://doi.org/10.17504/protocols.io.mrxc57n)

Phenol-Chloroform

Reagents	Catalogue Number
Buffer G2	Digestion Buffer. Qiagen cat. no. 19060
Proteinase K (10 mg/ml)	Qiagen cat. no. 19131
TE-saturated phenol	Sigma Aldrich cat. no. 77607
Chloroform-isoamyl alcohol	Sigma Aldrich cat. no. 25666
Ammonium acetate [5 M]	ThermoFisher cat. no. AM9070G
Ethanol 96%	
Ethanol 70%	
Tris-HCl, pH 8.0 [10 mM]	ThermoFisher cat. no. 15568025

Equipment
Heat block / water bath
Centrifuge
Eppendorf tubes (1.5 ml)
Glass or plastic hook
Pipettes and pipette tips P2, P10, P20, P100, P200, P1000
Starstedt (PP) Falcon tube 50 ml, 15 ml

List of Consumables: DNA Purification and Size Selection

Brandt (2019)

Protocol: Long-read DNA preparation for Metagenomic samples V.1

Protocols.io: [dx.doi.org/10.17504/protocols.io.w7afhie](https://doi.org/10.17504/protocols.io.w7afhie)

AMPure XP Purification

Reagents	Catalogue Number
Agencourt AMPure XP	Beckman Coulter cat. no. A63880
Nuclease-free water	
Ethanol 80%	

Equipment
LoBind Eppendorf tubes (1.5 ml)
Magnetic rack
Microcentrifuge
Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

Circulomics, MD, USA

Circulomics Short Read Elimination Kit (cat. no. SKU SS-100-101-01)

Reagents

Buffer SRE

Buffer EB

Ethanol 96%

Equipment

Centrifuge

Heat block

LoBind Eppendorf tubes (1.5 ml)

Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

List of Consumables: ONT Library Preparation

ONT, Oxford, UK

Protocol: 1D Genomic DNA by Ligation (SQK-LSK109)

Version: GDE_9063_v109_revD_23May2018

Ligation Sequencing Kit (cat. no. SQK-LSK109)

Flow Cell Priming Kit (cat. no. EXP-FLP001)

Kit Contents

DNA control strand (DCS)

Ligation Buffer (LNB)

Adapter Mix (AMX)

Long Fragment Buffer (LFB)

Elution Buffer (EB)

Sequencing Buffer (SQB)

Loading Beads (LB)

Flush Buffer (FB)

Flush Tether (FLT)

Additional reagents

Agencourt AMPure XP beads

NEBNext® FFPE Repair Mix

NEBNext cat. no. M6630

NEBNext® Ultra II™ End repair/dA-tailing Module

NEBNext cat. no. E7546

NEBNext® Quick Ligation Module

NEBNext cat. no. E6056

Ethanol 70%

Nuclease-free water

Equipment
LoBind Eppendorf tubes (1.5 ml)
Magnetic rack
Microcentrifuge
Vortex
Heat block
Ice bucket
Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

Quick (2018)

Protocol: One-pot ligation protocol for Oxford Nanopore libraries

Protocols.io: dx.doi.org/10.17504/protocols.io.k9acz2e

Ligation Sequencing Kit (cat. no. SQK-LSK109)

Flow Cell Priming Kit (cat. no. EXP-FLP001)

Kit Contents

DNA control strand (DCS)
Ligation Buffer (LNB)
Adapter Mix (AMX)
Long Fragment Buffer (LFB)
Elution Buffer (EB)
Sequencing Buffer (SQB)
Loading Beads (LB)
Flush Buffer (FB)
Flush Tether (FLT)

Additional reagents

Agencourt AMPure XP beads	
NEBNext® FFPE Repair Mix	NEBNext cat. no. M6630
NEBNext® Ultra II™ End repair/dA-tailing Module	NEBNext cat. no. E7546
NEBNext® Ultra II™ Ligation Module	NEBNext cat.no. E7595
Ethanol 70%	
Nuclease-free water	

Equipment

LoBind Eppendorf tubes (1.5 ml)
Magnetic rack
Microcentrifuge
Vortex
Heat block
Ice bucket

Kit Contents

Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

ONT, Oxford, UK

Protocol: Rapid Sequencing (SQK-RAD004)

Version: RSE_9046_v1_revD_17Nov2017

Rapid Sequencing Kit (cat. no. SQK-RAD004)

Flow Cell Priming Kit (cat. no. EXP-FLP001)

Kit Contents

Fragmentation Mix (FRA)

Rapid Adapter (RAP)

Sequencing Buffer (SQB)

Loading Beads (LB)

Flush Buffer (FB)

Flush Tether (FLT)

Additional reagents

Nuclease-free water

Nuclease-free water

Heat block

LoBind Eppendorf tubes (1.5 ml)

Microcentrifuge

Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

ONT, Oxford, UK

Protocol: Rapid Barcoding Sequencing (SQK-RBK004)

Version: RBK_9054_v2_revE_23Jan2018

Rapid Sequencing Kit (cat. no. SQK-RBK004)

Flow Cell Priming Kit (cat. no. EXP-FLP001)

Kit Contents

Fragmentation Mix (RB01-12)

Rapid Adapter (RAP)

Sequencing Buffer (SQB)

Loading Beads (LB)

Flush Buffer (FB)

Flush Tether (FLT)

Additional reagents

Nuclease-free water

Nuclease-free water

Heat block

Kit Contents

LoBind Eppendorf tubes (1.5 ml)

Microcentrifuge

Pipettes and pipette tips P2, P10, P20, P100, P200, P1000

List of Consumables: Flow Cell Wash and Nuclease Flush

ONT, Oxford, UK

Protocol: Washing flow cells

Version: WKE_1012_v1_revN_08Apr2016

Flow Wash Kit (cat. no. EXP_WSH002)

Kit Contents

Solution A

Storage Buffer (S)

Additional reagents

Buffer A	300 mM KCl ₂ ; 2 mM CaCl ₂ ; 10 mM MgCl ₂ ; 15 mM HEPES, pH 8.0
----------	--

DNase I	NEBNext cat. no. M0303
---------	------------------------

Nuclease-free water

Eppendorf tubes (1.5 ml)

Pipettes and pipette tips P100, P200, P1000

Appendix 2

Appendix 3

Oxford Nanopore Sequencing Cost Breakdown

Cost per new sequencing run

Flow cell	\$900.00
SQK-LSK109 per reaction	\$99.80
Total	\$999.83

Flow cell wash cost

EXP_WSH002 per wash	\$15.75
DNase I per reaction	\$6.26
Total	\$22.01

Cost per sequencing run with flow cell wash

Flow cell	\$900.00
SQK-LSK109 per reaction	\$99.80
SQK-LSK109 or SQK-RAD004 per reaction	\$99.80
Flow cell wash cost	\$22.01
Total	\$1,121.67

Cost per Gbp (new sequencing run)

New sequencing run	\$999.80	5.2 Gbp (average)
Total per Gbp	\$192.26	

Cost per Gbp (run with flow cell wash)

Sequencing run with flow cell wash	\$1,121.67	5.2 Gbp (new flow cell) 1.9 Gbp (used flow cell) 7.1 Gbp (total Gbp)
Total per Gbp	\$157.98
